Presence of co-morbidities
COPD, bronchiectasis, malignancy, diabetes mellitus, chronic renal failure, congestive heart failure, chronic liver disease, chronic alcohol abuse, malnutrition, cerebrovascular disease, post-splenectomy, hospitalisation within the past one year
Physical findings
Tachypnoea (30/min)
Hypotension (90/60 mm Hg)
Tachycardia (125/min)
Temperature <35 °C or >40 °C
Disorientation, clouding of consciousness
Laboratory findings
WBC <4 × 10^9/L or >30 × 10^9/L or an absolute neutrophil count below 1 × 10^9/L
Hypoxaemia and/or hypercapnia
Chest radiograph: multilobar involvement, cavity, presence of pleural effusion
Anaemia of (<9 mg/dL)
Organ dysfunction, other than respiratory
Acidosis (pH <7.35)

***C**onfusion, **U**rea (>7 mmol/L), **R**espiratory, **B**lood pressure and Age – is described as CURB65. COPD = Chronic obstructive pulmonary disease; WBC = White blood cell.*

Table 4: Treatment Options in Patients with Community Acquired Pneumonia

Patient Type	Preferred Treatment Options
Out-patients previously healthy	
No recent antibiotic therapy	A macrolide (erythromycin) or doxycycline
Recent antibiotic therapy	A respiratory fluoroquinolone alone (moxifloxacin levofloxacin/gemifloxacin) Macrolide (clarithromycin/azithromycin) plus high-dose amoxicillin, (1 g thrice a day) or an advanced macrolide plus high-dose amoxicillin-clavulanate (1.2 g thrice a day)
Co-morbidities (COPD, diabetes, renal or congestive heart failure or malignancy)	
No recent antibiotic therapy	An advanced macrolide or respiratory fluoroquinolone
Recent antibiotic therapy	A respiratory fluoroquinolone alone or an advanced macrolide plus a β-lactam (regimen selected will depend on nature of recent antibiotic therapy)
Suspected aspiration with infection	Amoxicillin-clavulanate or clindamycin
Influenza with bacterial super infection	A β-lactam or a respiratory fluoroquinolone
In-patients medical wards	
No recent antibiotic therapy	A respiratory fluoroquinolone alone or an advanced macrolide plus a β-lactam
Recent antibiotic therapy	An advanced macrolide plus a β-lactam or respiratory fluoroquinolone alone (regimen selected will depend on nature of recent antibiotic therapy)
Intensive care unit	
Pseudomonas infection is not an issue	A β-lactam plus either an advanced macrolide or a respiratory fluoroquinolone
Pseudomonas infection is not an issue but patient has a β-lactam allergy	A respiratory fluoroquinolone, with or without clindamycin
Pseudomonas infection is an issue	Either an anti-pseudomonal agent plus ciprofloxacin, or an anti-pseudomonal agent plus an aminoglycoside plus a respiratory fluoroquinolone or a macrolide
Pseudomonas infection is an issue but patient has a β-lactam allergy	Either aztreonam plus levofloxacin or aztreonam plus moxifloxacin or gatifloxacin, with or without an amino-glycoside

Complications need treatment as these arise (cross reference for treatment of empyema, respiratory failure, sepsis). Indications for mechanical ventilation (MV) (either non-invasive or invasive) in the management of pneumonia remains the same as for any other patient with respiratory failure.

HOSPITAL-ACQUIRED AND VENTILATOR-ASSOCIATED PNEUMONIA

HAP is defined as pneumonia that occurs after the patient has been in hospital for more than 48 hours. Patients who have been endotracheally intubated have a much higher risk of pneumonia. Endotracheal tube and MV and other intubations compromise the host defence mechanism seriously. The infecting organism is more likely to be an antibiotic resistant bacteria, especially when the patient has received frequent courses of antibiotics in the recent past, either at home or in a hospital, or has been on immunosuppressive therapy or haemodialysis (**Table 5**).

A relatively new term health care associated pneumonia (HCAP) is now being used to include any patient who was hospitalised in an acute care hospital for two or more days within 90 days of present infection; resided in a nursing home or long care facility, received intravenous antibiotics, chemotherapy or wound care within 30 days, or attended a hospital or haemodialysis clinic.

Table 5: Risk Factors for Multidrug-resistant Pathogens

Recent antibiotics
Prolonged hospitalisation
Prevalence of antibiotic resistance in the specific hospital unit
Recent hospitalisation (within last 3 months)
Intravenous infusion and antibiotics
Haemodialysis
Immunosuppression

DIAGNOSTIC TESTS

Bronchoscopic samples (protected specimen brush, broncho-alveolar lavage) are more specific, but non-bronchoscopic techniques, mainly tracheal aspirate, are cheaper. Physicians ability to diagnose VAP is often poor, as several pulmonary diseases may present with similar clinical signs. The presence of clinical signs of pneumonia in ICU patients (fever, pulmonary infiltrates in the chest radiograph and purulent pulmonary secretions) is caused by VAP in only about 30% to 40% of cases. Microbiologic findings may help to tailor antibiotic spectra in selected patients, but they should be considered in conjunction with a re-assessment of clinical response within 48 to 72 hours of onset of pneumonia. There is a problem of differentiating colonisation from infection. As a rule, colony forming units (CFU) of $\geq 10^3$/mL or $\geq 10^4$/mL or $\geq 10^5$ of protected brush, alveolar lavage, and tracheal aspirate respectively, are considered to indicate infection.

Depending on the clinical background, it is possible to predict antibiotic resistant bacteria. HAP and VAP are considered to be preventable (**Table 6**) if the quality of care had been optimal. The rates of nosocomial infections, when available, are used to compare units or countries and to assess a quality improvement programme in a given unit. In the context of our country, both *Klebsiella* and *Acinetobacter* are being seen with increasing frequency in the recent years.

Table 6: Recommended Measures for Prevention of Ventilator Associated Pneumonia

Hand disinfection
Microbiologic monitoring
Avoiding of invasive devices
Reduce antimicrobial prescriptions
Avoidance of endotracheal intubation
Non-invasive ventilation whenever possible
Preference of orotracheal intubation and orogastric tubes
Maintenance of optimum ET cuff pressure

PNEUMONIA IN IMMUNOCOMPROMISED PATIENTS

It is a more difficult problem to handle. The causative organisms are many and are unusual pathogens in addition to the common organisms we handle every day (**Table 7**).

Symptoms and Signs

Symptoms and signs are likely to be the same as those found with CAP or HAP in immunocompetent patients, though immunocompromised patients may have no fever or respiratory signs and are less likely to have purulent sputum if they are neutropaenic. In some patients, the only sign is fever.

Table 7: Pneumonia in Immunocompromised Patients

Disorders	Likely Pathogens
Acute leukaemia, aplastic anaemia, cancer chemotherapy	Gram-negative bacteria, *Staphylococcus aureus, Aspergillus sp., Candida sp.*
Diabetes mellitus	*S.aureus*, Gram-negative aerobes
Hodgkin's lymphoma, cancer haemotherapy, corticosteroid therapy	Mycobacteria, viruses (herpes simplex virus, cytomegalovirus), *Strongyloides sp.*, opportunistic fungi *(Aspergillus, Mucor, Cryptococcus spp), Nocardia sp., Toxoplasma sp.*
AIDS	*Pneumocystis jirovecii, Toxoplasma sp,* cytomegalovirus, herpes simplex virus, opportunistic fungi *(Aspergillus, Mucor, Cryptococcus spp),* mycobacteria
Multiple myeloma, agammaglobulinaemia	*S. pneumoniae, H. influenzae, Neisseria meningitidis*

Diagnosis

Diagnosis is established by chest radiograph, blood gases, bronchoscopy and lavage, an induced sputum and blood cultures.

It is to be kept in mind that an abnormal chest radiograph in these patients may not be due to an infection, there may be other reasons like haemorrhage, pulmonary oedema, tumour secondaries, radiation pneumonitis and pulmonary toxicity due to drugs.

Pneumocystis jirovecii is a common cause of pneumonia in immunosuppressed patients, especially in those infected with HIV and in those receiving systemic corticosteroids (see Chapter on HIV).

Chest radiograph showing localised consolidation usually indicates an infection involving bacteria, mycobacteria, fungi, or *Nocardia sp.* (**Figure 1**). A diffuse interstitial pattern is more likely to represent a viral infection, *P. jirovecii* pneumonia, drug or radiation injury, or pulmonary oedema. Diffuse nodular lesions suggest mycobacteria, *Nocardia sp.*, fungi, or tumour. Cavitary disease suggests mycobacteria, *Nocardia sp.*, fungi, or bacteria.

In organ or marrow transplantation recipients with bilateral interstitial pneumonia, the usual cause is CMV, or the disease is idiopathic. A pleural-based consolidation is usually aspergillosis. In AIDS patients, bilateral pneumonia is usually *P. jirovecii* pneumonia. About 30% of patients with HIV infection have *P. jirovecii* pneumonia as the initial AIDS-defining diagnosis, and >80% of AIDS patients have this infection at some time if prophylaxis is not given. Patients with HIV infection become vulnerable to *P. jirovecii* pneumonia when the CD4+ helper cell count is <200/μL.

Treatment

In neutropeenic patients, empiric treatment depends on the host defense, chest radiograph, and severity of illness. Generally,

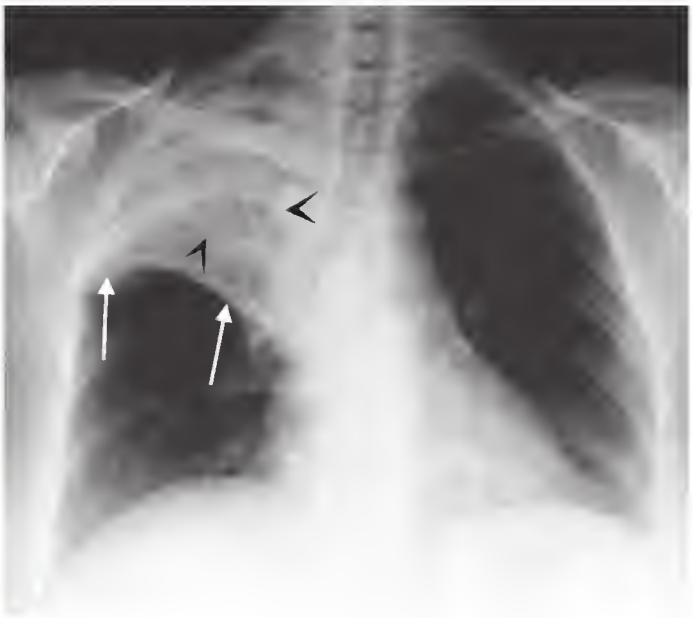

Figure 1: Chest radiograph (postero-anterior view) showing air bronchogram (black arrowheads) and pulled up fissures (white arrows) in case of right upper lobe bacterial pneumonia.

broad-spectrum drugs are needed to cover Gram-negative bacilli, *Staphylococcus aureus*, and anaerobes, as for HAP. If patients with conditions other than HIV do not improve with 5 days of antibiotic therapy, antifungal therapy is frequently added empirically.

Treatment of *P. jirovecii* infection is with antibiotics, usually trimethoprim-sulfamethoxazole or dapsone-trimethoprim, clindamycin-primaquine, atovaquone, or pentamidine. Patients with PaO_2 <70 mm Hg should receive systemic corticosteroids. Prognosis is generally good with timely treatment.

NON-RESOLVING OR SLOWLY RESOLVING PNEUMONIA

Normal resolution of pneumonia is variable and depends on the causative agent and the host response to the invading pathogen. Resolution of fever, white blood cell count, physical signs and radiographic changes usually occur in that order. Non-resolving pneumonia has been variably defined. Radiological resolution of the consolidation is usually achieved in *S. pneumoniae*, CAP by 4 weeks in most patients, but in some, it might take up to 10 weeks. Physicians are often confronted with the problem of non-resolving pulmonary infiltrates in patients receiving antibiotics for CAP.

Atypical organisms, TB and fungal infections need to be excluded, but the main emphasis in clinical practice is to exclude non-infectious causes to explain non-resolving pulmonary infiltrates (**Table 8**).

Table 8: Non-Infectious Mimics of Pneumonia

Neoplasms
Cryptogenic organising pneumonia or bronchiolitis obliterans with organising pneumonia
Hypersensitivity pneumonitis
Eosinophilic syndromes
Pulmonary vasculitides
Alveolar haemorrhagic syndromes
Pulmonary alveolar proteinosis

PREVENTION OF PNEUMONIA

All persons above the age of 50 years should receive inactivated influenza vaccine. Influenza vaccine should also be offered to all patients at hospital discharge and health care workers in in-patient and out-patient settings and in long-term care facilities should receive annual influenza immunisation (not evidence based).

Pneumococcal polysaccharide vaccine is recommended for use in persons aged >65 years and for younger adults with co-morbid diseases like diabetes, cardiovascular disease, lung disease, alcohol abuse, liver disease, cerebrospinal fluid leaks or renal failure. It is also recommended for patients with immune system disorders like sickle cell disease, nephritic syndrome, HIV infection, haematological malignancies and those who are on long-term immunosuppressive therapy.

Older adults may be benefitting from vaccination of children against pneumococcal disease because of decreased pneumoeoccal transmission. A pneumococcal conjugate vaccine is available for use only in children and according to data had resulted in 69% lower incidence of invasive (primary bacteraemic pneumonia with bacterial meningitis) pneumococcal disease in children under 2 years.

23.8 Suppurative Pleuro-Pulmonary Diseases

Dheeraj Gupta, Navneet Singh

Suppurative pleuro-pulmonary diseases continue to cause significant morbidity and mortality despite considerable advances made in the diagnosis and management of these conditions. The major suppurative lung diseases are bronchiectasis, lung abscess and empyema.

BRONCHIECTASIS

Introduction and Epidemiology

Bronchiectasis (BE) (*broncos* ~ airways; *ectasia* ~ dilation) is defined as an abnormal, irreversible dilatation of the bronchi. Strictly speaking, it is not a disease *per se* but the end stage of a variety of pathologic processes. Since, the primary clinical manifestations of BE are recurrent, chronic and sometimes refractory infections, it is discussed along with other suppurative diseases of the lung.

Classification

Aetiological

The aetiological classification of bronchiectasis is listed in **Table 1**.

Pathological/radiological

Three main types are described—(i) tubular or cylindrical (**Figure 1**), (ii) varicose and (iii) cystic (saccular) (**Figure 2**) depending upon the appearance of dilated bronchi on imaging. These three types largely represent increasing severity of the disease.

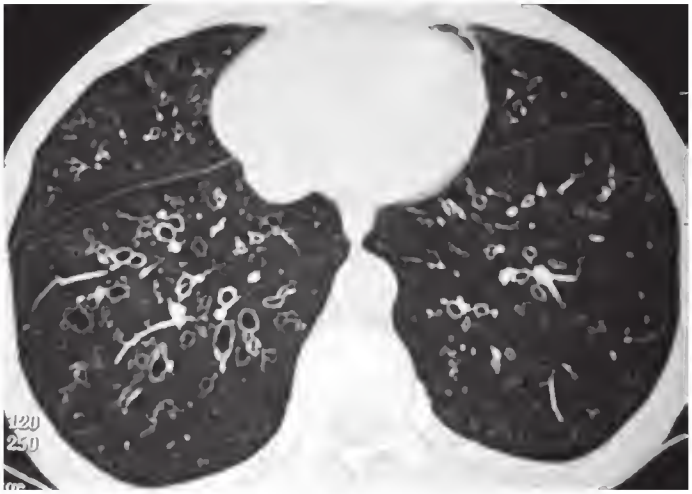

Figure 1: HRCT chest showing tubular bronchiectasis with a central distribution in both lower lobes.

Extent

Bronchiectasis can be either focal or diffuse. Focal or localised disease is typically seen when bronchiectasis results from mechanical bronchial obstruction.

Pathophysiology

Chronic inflammation involving the medium sized bronchi and bronchioles is the hallmark of bronchiectasis. On histopathology,

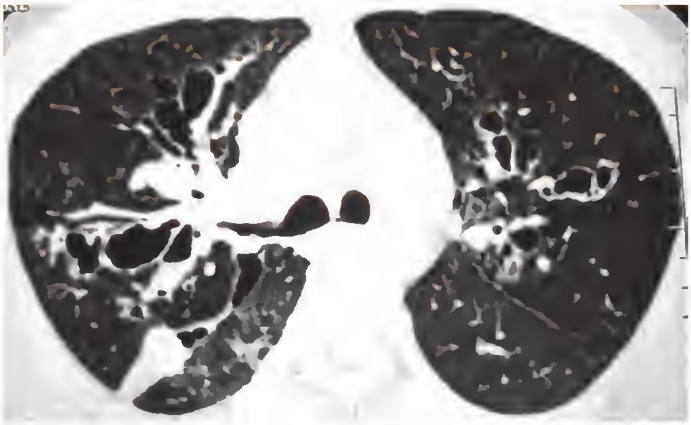

Figure 2: HRCT chest showing varying degrees of varicose and saccular bronchiectasis in both lungs.

there is exudation of neutrophils into the lumina of affected airways as well as infiltration of the bronchial/bronchiolar wall by neutrophils, mononuclear cells and CD4+ T lymphocytes. Recruitment of neutrophils is mediated by proinflammatory cytokines (IL-1β, IL-8, TNF-α and LT B4). Activation of neutrophils leads to damage to the respiratory mucosa and stimulation of mucous secreting glands in the airways. This is followed by a reduction in ciliary beating, impaired mucociliary clearance and ultimately retention of inflammatory secretions. Local immune response to inhaled pathogens becomes deficient and this results in colonisation of the bronchial tree by bacteria like *Pseudomonas aeruginosa*. Thus, infection, inflammation and airway damage perpetuate each other by a vicious cycle.

Clinical Features

The characteristic symptoms of bronchiectasis are chronic cough with expectoration, the sputum being typically copious, thick and purulent. However, the sputum may also be mucoid, mucopurulent or tenacious. This symptom is present in majority (up to 95%) of the patients and the quantity of sputum correlates with the quality of life (QoL). Associated rhino-sinusitis is present in two-thirds of cases. Dyspnoea and chest pain are other common symptoms. Haemoptysis is seen in 30% of patients and can vary from mild blood streaking of sputum to massive haemoptysis. The most common findings on physical examination are crackles (78%) and wheezing (20%). Digital clubbing, a frequent finding in the past, was seen in less than 5% of patients in a recent review.

Investigations

Radiology

Chest radiograph: Chest radiography is a relatively insensitive tool for diagnosing bronchiectasis. Specific findings include ring-like shadows (airways parallel to the X-ray beam), tram lines (airways perpendicular to the X-ray beam) and cystic lesions

(saccular bronchiectasis). However, other findings may be non-specific, e.g. atelectasis, focal area of consolidation and infiltrates.

Table 1: Aetiological Classification of Bronchiectasis

- **Post infectious**
  - Bacterial
    - *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Haemophilus influenzae*, anaerobes

    - Primary
      - Hypogammaglobulinaemia
      - Immunoglobulin G subclass deficiency
      - Complement deficiency
    - Secondary
      - Malignancy
      - Chemotherapy
      - Post-transplant
      - HIV infection
- **Mechanical bronchial obstruction**
  - Foreign body
  - Tumour
  - Lymphadenopathy
- **Sequelae of aspiration or inhalation of toxic gases**
- **Systemic diseases**
  - Collagen vascular diseases
    - Rheumatoid arthritis
    - Sjögren's syndrome
    - Ankylosing spondylitis
    - Relapsing polychondritis
    - Marfan's syndrome
  - Inflammatory bowel disease
- **Miscellaneous**
  - Diffuse panbronchiolitis
  - Yellow nail syndrome

HRCT thorax: High resolution computed tomography (HRCT) scanning is the investigation of choice for diagnosing bronchiectasis and has virtually replaced bronchography. The diagnostic signs are listed in **Table 2**. This is usually done as a non-contrast study using thin sections (1.0 to 1.5 mm window every 10 mm) and a fast scan time (image acquisition time typically of 1 second or less) during full inspiration to reduce artefacts induced by respiration and cardiac pulsation.

Table 2: Diagnostic Signs of Bronchiectasis on HRCT Scans

Major signs

- Bronchial dilatation (abnormal widening of bronchi)
  - Horizontal bronchi: internal diameter of bronchus greater than diameter of its adjacent pulmonary artery (typically 1.5 times or more)—***Signet Ring Sign***
  - Vertical bronchi: Non-tapering or flaring of bronchi towards the periphery—***Tram lines***
- Presence of bronchi in the outer lung fields (within 1 to 2 cm of pleura)

Minor signs

- Bronchial wall thickening
- Mucus impaction in dilated bronchi (with/without plugging of centrilobular bronchioles)
- Crowding of bronchi (volume loss of affected lobe)
- Areas of reduced attenuation (mosaic pattern)

Spirometry

Spirometry with bronchodilator reversibility testing and flow–volume loops should be done in all patients with suspected or proven bronchiectasis. Spirometry often shows an obstructive pattern. Significantly, almost one-third of patients also demonstrate presence of bronchodilator reversibility. Presence of a restrictive defect indicates presence of significant atelectasis, fibrosis or consolidation.

Sputum analysis

Patients with stable bronchiectasis commonly (usually 60% to 80%) have colonisation with micro-organisms in their airways. *Haemophilus influenzae* and *Pseudomonas aeruginosa* are the two most commonly isolated micro-organisms. Patients who have colonisation with *Pseudomonas aeruginosa* tend to have more severe disease.

Specific tests directed at ascertaining aetiology

These are listed in **Table 3,** although a detailed discussion about them is beyond the scope of this chapter.

Table 3: Tests for Detecting Specific Aetiologies of Bronchiectasis

- Paranasal sinus disease (X-ray or CT paranasal sinuses)
- Gastro-oesophageal reflux (barium swallow, 24 hours oesophageal pH monitoring, oesophageal manometry)
- Immune deficiency [Total levels of IgG (and subclasses), IgM, IgE and IgA]
- ABPA [*Aspergillus* skin test, serum precipitins against *Aspergillus fumigatus* and sputum for *Aspergillus fumigatus*]
- Connective tissue disorders (antinuclear antibodies and rheumatoid factor)
- α1-antitrypsin deficiency (serum α1-antitrypsin levels)
- Cystic fibrosis (sweat chloride analysis, nasal potential difference, genotyping)
- Endobronchial abnormalities (Fibre-optic bronchoscopy)
- Ciliary dyskinesias (semen analysis, nasal mucociliary clearance – saccharine test, respiratory cilia sampling followed by electron microscopy

Treatment

Antibiotics

In general, most infective exacerbations are caused by bacteria that are also common aetiological agents for acute

exacerbations of COPD namely *Haemophilus influenzae, Streptococcus pneumoniae* and *Moraxella catarrhalis* and thus, can be treated by conventional β-lactam antibiotics (penicillins and cephalosporins). Patients with *Pseudomonas aeruginosa* infection may need to be treated differently (including use of parenteral antipseudomonal drugs). Antimicrobial therapy should be guided by sputum cultures which are preferably taken before initiation of treatment since patients may have colonisation with multiple pathogens.

Controversies exist regarding the optimal dose, route and duration of antibiotic therapy.

Dose: Proponents for use of a higher (than usual) dose of antibiotics in bronchiectasis argue that the penetration of antibiotics into the bronchial mucosa and secretions is suboptimal and thus, micro-organisms that are shielded by them (formation of biofilms) do not get eradicated. However, evidence for higher doses is not yet conclusive.

Duration: In general, it is prudent to use antibiotics only during an acute infective exacerbation (generally for a period of 10-14 days). Hence, if clinical worsening is not associated with symptoms suggestive of an infective aetiology (increase in sputum quantity or purulence or fever), it is preferable to avoid using antibiotics. Even during stable disease, antibiotics have been used regularly (continuously or on a monthly basis). However, this has the potential drawback of promoting drug resistance and till conclusive evidence is available to support its role, it cannot be routinely advocated for management of bronchiectasis.

Route: Nebulised antibiotics have shown promise when used in patients with cystic fibrosis (CF) who are colonised by potentially pathogenic micro-organisms like *Pseudomonas aeruginosa* although recent studies have reported similar benefits even among patients with non-CF bronchiectasis. Aminoglycosides (especially tobramycin) are the drugs that have been most commonly used through the inhalational route.

Bronchopulmonary hygiene

Bronchopulmonary hygiene consists of pharmacological and non-pharmacological measures to assist the patient in removal of secretions from his/her respiratory tract.

Physiotherapy: Physiotherapy by postural drainage, chest percussion, forced exhalation and controlled cough is useful in clearing excessive secretions. Mechanical devices that cause chest vibration are also being increasingly used in developed countries.

Mucolytics: These are not recommended for routine use in non-CF bronchiectasis. Nebulised saline, human recombinant DNase and acetyl cysteine all have been shown to be beneficial only in patients with CF.

Surgery

Localised bronchiectasis that is associated with intractable symptoms despite optimal medical management may benefit from surgical resection of the affected segment or lobe.

Bronchodilators

Data on use of inhaled drugs is sparse. Inhaled corticosteroids (ICS), when used in high doses, have been shown (in small randomised trials) to have beneficial effects on symptom related parameters (sputum volume, sputum purulence, cough, dyspnoea) and QoL but without any changes in pulmonary function, number or severity of exacerbations, or microbiological profile of sputum. The benefit may be more marked in those with *Pseudomonas aeruginosa* infection. Therefore, at present their use may be restricted to patients showing significant reversibility of airway obstruction.

Complications

Important complications are recurrent pneumonia, empyema, lung abscess, pneumothorax, cor pulmonale and respiratory failure. Metastatic brain abscesses have also been reported. Secondary amyloidosis is an important long-term complication.

LUNG ABSCESS

Lung abscess is a circumscribed collection of purulent and necrotic material (pus) within the lung parenchyma. Most patients have a predisposition to either aspiration or systemic/local immune suppression.

Pathogenesis

Development of lung abscess can either be a primary (aspiration and bronchogenic spread of infection) or secondary (haematogenous spread to the lung) phenomenon.

The latter usually occurs in patients with an obvious focus of infection elsewhere in the body like endocarditis, liver and other visceral abscesses or suppurative thrombophlebitis. However, lung abscess can develop in patients who have asymptomatic bacteaemia.

In case of lung abscess occurring as a primary phenomenon, the initial process is aspiration of oropharyngeal contents. The aspirate commonly consists of the oropharyngeal flora (predominantly anaerobic bacteria), as well as food debris (and even necrotic periodontal tissue in case of patients with dental caries). Aspiration is followed by development of a pneumonitic process caused by the aspirated anaerobic bacteria. Over a period of 1 to 2 weeks, necrosis ensues and ultimately leads to the formation of a single or multiple cavities. The difference between necrotising pneumonia and lung abscess is only of theoretical interest since the underlying pathogenetic process is the same. In general, lung abscess implies a cavity that is at least 2 cm in diameter while necrotising pneumonia represents multiple, small cavities each of which is less than 2 cm in diameter. The suppurative process, if unchecked, can extend to the pleural space leading to empyema.

There are several factors that predispose to aspiration and lung abscess (**Table 4**); however, aspiration can occur in normal individuals also. When no predisposing factor is apparent, endobronchial obstruction (benign or malignant) should be ruled out.

Microbiology

Although more than 200 different species of micro-organisms constitute the resident flora in the oropharynx (gingival crevices), analysis of the lower respiratory tract secretions in patients with lung abscess reveals that the most virulent among

them (generally 4 to 5 in number) predominate. Anaerobic bacteria like *Prevotella melaninogenicus*, *Fusobacterium nucleatum* and *Peptostreptococcus* spp., are the most commonly isolated micro-organisms. A putrid (foul) odour of sputum is characteristic of anaerobic micro-organisms. Microaerophilic streptococci such as *Streptococcus milleri* are other important pathogens. In addition to anaerobes, aerobic Gram-negative bacilli (GNB) including *Klebsiella pneumoniae, Staphylococcus aureus* and *Pseudomonas aeruginosa* have an important role in the genesis of hospital acquired lung abscesses and their presence is often associated with a poor prognosis.

Table 4: Predisposing Factors for Development of Lung Abscess

Factors predisposing to aspiration
Impaired consciousness
Anaesthesia (general)
Alcohol intoxication
Dental caries
Drug overdose or abuse (narcotics, sedatives)
Head trauma
Metabolic encephalopathy (diabetic coma, hepatic and renal failure)
Neuromuscular diseases
Seizures including post-ictal state
Stroke (cerebro-vascular accident)
Oesophageal disorders
Achalasia and other dysmotility syndromes
Gastro-oesophageal reflux
Stricture (benign or malignant)
Zenker's diverticulum
Immune-suppression
Local
Chronic lung disease
Systemic (Impairment of cell mediated or humoral immunity)
Primary
Secondary
Diabetes mellitus
Malignancy
Chemotherapy
HIV infection
Mechanical bronchial obstruction
Foreign body
Tumour
Lymphadenopathy

Clinical Features

Most patients present with fever and cough with expectoration that is usually copious and foul smelling. Chest pain and haemoptysis are also frequent. Since the typical characteristics of sputum may not be present in all cases especially during the early course of infection, the clinical profile can mimic other diseases like tuberculosis and lung cancer.

Investigations

Radiology

Chest radiograph: Chest radiographs (postero-anterior and lateral views) help to confirm the presence of lung abscess and differentiate it from a pyopneumothorax although at times, this may be difficult and the two may even co-exist. A thick walled cavity with an air-fluid level is the commonly seen abnormality (**Figure 3**). In patients with necrotising pneumonia, consolidation with areas of breakdown in between (cystic lucencies) is seen.

Figure 3: Chest radiograph (PA view) showing a peripherally situated abscess in the left lower lobe with air-fluid level and surrounding consolidation. Few infiltrates are also seen in the left upper zone.

CECT thorax: Contrast enhanced computed tomography (CECT) of the chest (**Figure 4**) helps to define the number and location of abscess(es), as well as other associated features (parenchymal, interstitial, mediastinal or airway abnormalities), if any. In typical cases of lung abscess occurring after aspiration, the location of the abscess(es) is in the dependent broncho-pulmonary segments (superior segment of the lower lobe or posterior segment of the upper lobe when aspiration occurred in the supine position).

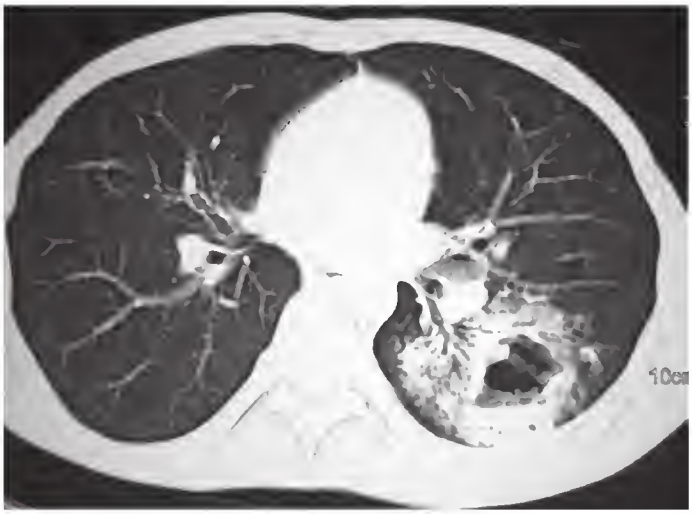

Figure 4: CT chest showing thick-walled abscess in the left lower lobe with air-fluid level and surrounding consolidation (air bronchogram).

Sputum analysis

Anaerobes are isolated in 60% to 80% (and even 100% in certain series) of respiratory tract specimens obtained from patients with lung abscess. Three-fourths of these are polymicrobial (multiple anaerobes or both anaerobes and aerobes).

Anaerobes are ubiquitous commensals of the oral cavity and hence, sputum cultures alone may be of little value in establishing the aetiological agent(s) of lung abscess. However, in routine clinical practice, invasive approaches to obtain lower respiratory tract specimens (transtracheal or transthoracic lung aspiration) are not recommended. A search

for non-conventional aetiological micro-organisms (aerobic GNB, *S. aureus*, *P. aeruginosa*, *Mycobacterium tuberculosis*, fungi, *Nocardia* sp.) should be done in cases of lung abscesses occurring in patients with diabetes mellitus, presenting with non-purulent sputum, multiple abscesses and lack of clinical improvement after 1 week of antibiotic therapy. Lung abscess due to *Rhodococcus equi* is characteristically seen in patients with AIDS. Apart from infectious causes, other causes for lack of response to therapy include presence of a cavitating neoplasm, cystic bronchiectasis and Wegener's granulomatosis all of which can mimic a lung abscess, clinically and radiologically. Such cases should undergo further investigations including bronchoscopy with/without collection of specimens by protected brushing, bronchoalveolar lavage (BAL) and bronchoscopic lung biopsy.

Treatment

Antibiotics

Antimicrobial therapy is the cornerstone of treatment in lung abscess. The optimal duration of antibiotic therapy for most suppurative pleuro-pulmonary diseases including lung abscess is generally 6 to 8 weeks.

Clindamycin has been the preferred drug for treatment of lung abscess in view of its superiority to penicillin in terms of rates of response, duration of fever and time to resolution of putrid sputum. However, lately β-lactam/β-lactamase inhibitor combinations have been proven to be equally effective. Metronidazole is generally ineffective against microaerophilic streptococci limiting its usefulness. A combination of penicillin and metronidazole may be used in situations when there is no access to better antibacterial drugs.

A prospective, open, randomised multicentre trial that compared ampicillin and sulbactam with clindamycin (with/without a 2nd/3rd generation cephalosporin) found that both were well-tolerated and equally efficacious in the treatment of aspiration pneumonia and lung abscess.

Drainage

Postural drainage and chest physiotherapy have been used previously as adjuncts to antimicrobial therapy in an attempt to bring out purulent contents of the abscess cavity. However, this is associated with the danger of inducing sudden emptying of the cavity and the large quantity of expectorated purulent and necrotic material can fill up the airways, as well as the previously uninvolved bronchopulmonary segments with catastrophic consequences.

Percutaneous catheter drainage: In 10% to 20% of patients with lung abscesses who do not respond to medical therapy, percutaneous catheter drainage of the abscess under CT guidance has been used. The usual indications are enlarging cavity and a peripheral location. Obvious risks are creation of a pneumothorax or even pyopneumothorax. Catheter occlusion is another problem especially if the abscess contents are thick and viscid. Overall, complications relating to the procedure occur in approximately one out of 10 cases.

Endoscopic drainage: Endoscopic lung abscess drainage is an alternative to percutaneous catheter drainage for patients with lung abscess in whom conventional medical management (antibiotic therapy) is unsuccessful. Presence of a communication between the lung abscess and the airways is essential for successful insertion of the catheter.

Surgery

Surgical resection is reserved for individuals if the non surgical drainage techniques mentioned above are either not feasible or not available. The rare complication of massive haemoptysis may also mandate surgical intervention.

Outcome and Prognostic Indicators

Complications are generally rare if appropriate and timely antimicrobial therapy is instituted. Complications can be local e.g. empyema, alveolopleural fistulas and recurrent haemoptysis or systemic e.g. metastatic abscesses, infective endocarditis, sepsis and amyloidosis. Predictors of poor outcome are listed in **Table 5**. The overall mortality rate secondary to lung abscess is 5% to 20%.

Table 5: Factors Predictive of Poor Outcome in Lung Abscess

Abscess characteristics
Secondary origin
Large abscess size (>6 cm diameter) and volume
Multiple abscesses
Location in right lower lobe
Host factors
Advanced age
Altered consciousness
Anaemia (haemoglobin <10 g/dL) at admission
Immunosuppression
Malignancy (pulmonary or extra-pulmonary)
Malnutrition and debilitation
Pneumonia
Symptom duration >8 weeks
Microbiological factors—Infection by aerobic organisms alone
Pseudomonas aeruginosa
Staphylococcus aureus
Klebsiella pneumoniae

EMPYEMA THORACIS

Introduction and Epidemiology

Collection of pus in the pleural cavity is known as *thoracic empyema* or *empyema thoracis*. Most empyemas occur as a complication of parapneumonic effusion (PPE). The incidence of thoracic empyema has reduced with the use of effective antibiotics for acute pneumonia.

Pathogenesis

The pleural space is normally sterile and not exposed to environmental (inhaled) pathogens. Pyogenic organisms can gain access to this space by local spread of infection from a focus in either intra- or extra-thoracic areas. Empyema occurring in the absence of clinical and radiological evidence of pneumonia (or other obvious focus of infection) is called primary empyema.

After invasion of the pleural space, suppuration ensues if the invading organisms are able to overcome the natural defence and immune mechanisms. The high concentration of leucocytes in the empyema fluid along with fibrin, cellular debris and bacteria (living or dead) are responsible for its characteristic thick, viscous, whitish-yellow, opaque and turbid appearance (pus). However, pleural invasion by a pyogenic micro-organism does not always progress to empyema. In fact, simple

(uncomplicated) PPE and empyema are two ends of a continuous spectrum (**Table 6**). The formation of PPE can be divided into 3 stages—exudative, fibropurulent and organisation stages. Increased permeability of the visceral pleura is responsible for the development of a sterile exudative effusion in the first phase (simple PPE). The second phase is marked by infection of the exudate, fibrin deposition over the pleura and tendency for formation of loculations/adhesions. In third phases, there is influx of fibroblasts into the pleural space, formation of dense and inelastic pleural peel/fibrous septations.

Table 6: Comparison of Parapneumonic Effusions and Empyema

Fluid Characteristic	Simple PPE	Complicated PPE	Empyema
Visual appearance	Clear	Clear to turbid	Frank pus
pH	>7.2	<7.2	**
LDH	<1000 IU/L	>1000 IU/L	**
Glucose*	>40 mg/dL	<40 mg/dL	**
Neutrophils	Usually <10,000/mL	Usually >10,000/mL	**
Gram stain	Negative	May be positive	Usually positive
Quantity	Minimal (<10 mm on lateral decubitus CXR)	Small to moderate (>10 mm on lateral decubitus CXR but occupying <1/2 hemithorax)	Large (>1/2 hemithorax) OR Any quantity with associated loculations/ thickening of visceral pleura
Free-flowing	Yes	Yes (usually)	Often loculated
Drainage required	Usually no	Yes	Yes

*PPE = parapneumonic effusion; *Fluid glucose <25% blood glucose can be taken as surrogate for absolute value; ** Not applicable.*

Among the biochemical tests in diagnosing PPEs, pH is the most accurate followed by glucose and then lactate dehydrogenase (LDH).

Microbiology

Microbiological profile in thoracic empyema is similar to lung abscess, dominated by polymicrobial isolation from clinical specimens and predominance of anaerobic bacteria. The latter are responsible for 25% to 76% of cases of empyema and in approximately 30% to 35% of cases, there is no associated aerobic infection.

Clinical Features

Patients may present with fever, chest pain, cough, constitutional symptoms or any combination of these. Cough is usually dry unless a large alveolopleural fistula results in copious postural expectoration of pus or there is underlying necrotising pneumonia. On physical examination, specific signs (in addition to those seen in any pleural effusion) include chest wall tenderness and rib crowding.

Investigations

Radiology

Chest radiograph and ultrasound: Typical finding on a PA film is that of a loculated pleural effusion. An air-fluid level may be seen in the presence of an air-leak. In certain cases, it may appear as a rounded pleural mass simulating lung cancer or mesothelioma. Lateral (decubitus or erect) radiographs may be used in addition to PA films. However, the availability of ultrasound has virtually replaced the need for these. Ultrasound is very good modality for evaluation of pleural space and can also be used for diagnostic or therapeutic drainage of loculated empyema.

Contrast enhanced CT (CECT) thorax: Pleural thickening and enhancement on CECT is seen in 80% to 100% of empyemas. The 'split-pleura' sign (presence of thickened enhancing parietal and visceral pleura separated by pleural fluid) is a characteristic finding (**Figure 5**). There is however, no correlation between the extent of pleural thickness and response to treatment.

Figure 5: CECT chest showing the split-pleura sign seen in a patient with bilateral empyema.

Pleural fluid/pus culture

Pleural fluid culture is positive in approximately 60% of cases and much less for anaerobic organisms. Yield may be enhanced by putting pleural fluid samples into blood culture bottles and by taking concomitant blood samples for culture.

Treatment

In contrast to the other suppurative lung diseases (bronchiectasis and lung abscess) wherein antibiotics form the cornerstone of management, antimicrobial therapy alone is inadequate for the treatment of patients with empyema and has to be supplemented with adequate drainage of pus.

Antibiotics

In general, principles of antimicrobial therapy in empyema are the same as those for lung abscess. Appropriate anaerobic cover and adequate duration, both are of paramount importance.

Drainage

Intercostal tube drainage (ICTD) is the most common method for drainage. It is a common belief that relatively large (28 to 36 French) chest tubes are better than smaller bore ones in view of the tendency for chest tubes to get obstructed by the thick fluid. However, correct positioning of the chest tube is more important than its size since studies that have used 8-12 F pigtail catheters under ultrasound or CT guidance have given comparable results to larger bore tubes.

Therapeutic thoracentesis (preferably daily) may be considered as an alternative to ICTD when the latter is either unavailable or contra-indicated due to any reason (e.g. presence of coagulopathy or bleeding diathesis). However, there are no randomised-controlled trials that have compared it with formal drainage.

Fibrinolytics

Incomplete pleural drainage is often seen with ICTD either due to tube occlusion or multiple fibrinous loculations in the pleural space. Use of intrapleural fibrinolytic agents in such individuals may, by lysing fibrin clots and adhesions, facilitate pleural drainage and thus, obviate the need for more invasive surgical interventions.

In a recent Cochrane review, it was concluded that intrapleural fibrinolytic therapy confers significant benefit in reducing the requirement for surgical intervention. Indian studies have also shown intrapleural streptokinase to be a safe and effective adjunctive therapy for patients with empyema and complicated PPE. Fibrinolytics and other biological agents that can be used to enhance drainage of pleural space collection and prevent development of pleural fibrosis (as adjuncts to drainage and antimicrobial therapy) are listed in **Table 7**.

Table 7: Biological Agents for the Treatment of Empyema Thoracis

Fibrinolytics
Streptokinase
Urokinase
Tissue plasminogen activator (Alteplase t-PA)
Single-chain urokinase plasminogen activator
Deoxyribonucleases
Streptodornase
Human recombinant DNase
Antibodies against specific growth factors
Antibody against transforming growth factor (TGF)
Antibody against vascular endothelial growth factor (VEGF)

Surgery

Surgical intervention may be required in as high as 40% of patients with empyema in whom medical management alone is unsuccessful and can be any of the options mentioned below. Although the optimal timing of surgical intervention remains a controversial area, it can be considered as early as seven days after initiation of conservative treatment.

Thoracotomy and decortication: Thoracotomy with decortication has remained the 'gold' standard of surgical management of empyema in the past. However, decortication is a major surgical procedure and is associated with significant morbidity since it involves removal of the fibrous peel covering the visceral and parietal pleura, as well as evacuation of all pus and debris from the pleural cavity. Hence, in the acute stages, decortication should only be done only for control of pleural infection and not for thickened pleura because the latter usually resolves spontaneously with time. If thickening of pleura persists after six months and patient is experiencing significant limitation of activities/restrictive pulmonary defects attributable to the former, decortication should be considered. Marked debilitation, understandably, is a relative contra-indication.

Rib resection and open thoracic drainage: Open thoracic drainage (after resection of segments of 1 to 3 ribs overlying the lower part of the empyema cavity) can be achieved in several ways (**Table 8**).

Table 8: Open Drainage Procedures for Empyema Thoracis

Insertion of one or more short, large-bore tubes into the empyema cavity followed by daily irrigation with an antiseptic solution and collection of the drainage into a colostomy bag placed over the tube(s)
Packing of the empyema cavity with gauze
Open (Eloesser) flap procedure—Creation of a fistulous tract between the empyema cavity and the chest wall that is covered by a skin and muscle flap

The aim in each of them is to allow drainage of the pleural space over a prolonged period of time while allowing the patient to be domiciliary, mobile and at the same time promoting gradual obliteration of the pleural space. Advantages of the two procedures includes chest drainage without tubes and thus, more patient freedom and often more complete drainage.

An important precaution to be taken before undertaking these procedures is to ensure that visceral and parietal pleura adjacent to the empyema cavity have become fused by the chronic inflammation otherwise a pneumothorax will result when the pleural space is in open communication with the atmospheric pressure. Therefore, these procedures cannot be performed early in the course of a complicated PPE/empyema.

Thoracoscopy

Video-assisted thoracoscopic surgery (VATS) is increasingly being used as an alternative to open thoracotomy primarily because it is less invasive and, thus, has less procedure-related morbidity and mortality. VATS allows the operator to break adhesions and loculations in the pleural space, ensure complete drainage of fluid/pus and place ICTD in the most appropriate location, as well as attempt decortication. VATS can be converted to open thoracotomy if it is felt that the desired results cannot be achieved with the former. The biggest disadvantage is lack of its availability. Duration of chest drainage and hospital stay tend to be shorter than those occurring after open thoracotomy with decortication.

TUBERCULOUS EMPYEMA

Tuberculous empyema remains an important entity in India due to the high disease burden of tuberculosis. Tuberculous empyema differs from tuberculous pleural effusions in several aspects (**Table 9**).

Since the immune response is much less than that in patients with tuberculous effusions, there is often a paucity of clinical symptoms and patients may in fact present years after onset of infection. Disease may be suspected after a routine chest radiograph or subsequent to development of an alveolopleural fistula (APF) or empyema necessitates. The characteristic radiological findings include a thick, calcified pleura, rib crowding and loculated collections of pus. Management involves administration of anti-tuberculous therapy (ATT), as well as drainage of pleural space. However, poor penetration of drugs through the fibrotic calcified pleura into the empyema

cavity leads to sub-therapeutic drug concentrations sub-optimal and this tends to promote the development of drug resistance.

Table 9: Comparison of Tuberculous Pleural Effusion and Empyema

Characteristic	Tuberculous Pleural Effusion	Tuberculous Empyema
Incidence	Very common	Relatively rare
Pleural space infection	Localised	Diffuse
Manifestations due to	Exaggerated immune response	Chronic active infection
Visual appearance of fluid	Straw coloured	Frank pus
Predominant cells in fluid	Lymphocytes	Neutrophils
Mycobacterial load	Low (Paucibacillary)	High
Smear for AFB	Rarely positive (<20%)	Strongly positive
Whether drainage required	Usually no	Yes
Residual fibrosis and restrictive defects	Minimal/none	Significant

Another commonly encountered problem is the inability of the trapped lung to re-expand after conservative management and surgical interventions like decortication may be required to achieve this. However, surgery should be undertaken only by experienced thoracic surgeons since patients with tuberculous empyema are poor surgical candidates (**Table 10**).

Table 10: Problems with Performing Surgery for Tuberculous Empyema

- Pulmonary parenchymal involvement
- Malnutrition and generalised debilitation
- Higher risk for post-operative complications
  - Persistent air leak [alveolopleural fistula (APF)]
  - Secondary bacterial infections
  - Respiratory failure
  - Bronchial stump dehiscence
- Technically difficult surgery

High risk patients may be managed conservatively by prolonged tube thoracostomy (or pigtail drainage) along with ATT.

Patients with tuberculous empyema generally fare much worse than those with non-tuberculous empyema. A prospective study to compare the clinical characteristics and outcomes of empyema thoracis due to tuberculous and non-tuberculous aetiologies was carried out recently. Significant differences existed between the two groups (**Table 11**) although mortality rates were similar (approximately 10% in each group).

Overall, amongst patients with empyema, presence of any of the two factors (APF or tuberculous aetiology) was associated with a six-fold risk of having a poor outcome.

Table 11: Comparison Between Tuberculous and Non-Tuberculous Empyema

Characteristic	Tuberculous Empyema (n = 41)	Non Tuberculous Empyema (n = 76)
Prevalence of diabetes mellitus	39.0 %	5.3 %
Mean duration of symptoms	37.5 days	15 days
Prevalence of malnutrition (BMI <18.5 kg/m^2)	56.1 %	28.9 %
Persistent air leak (APF)	78.1 %	22.4 %
Use of intra-pleural streptokinase	4.9 %	23.7 %
Median duration of pleural drainage	55 days	14 days
Median time for resolution of fever	7 days	5 days
Incidence of residual pleural thickening >2 cm	95.1 %	63.2 %

AMOEBIC LUNG ABSCESS AND EMPYEMA

Thoracic amoebiasis (caused by *Entamoeba histolytica*) is an important cause of both empyema and lung abscess. The right lung (lower and middle lobes) is usually affected (>85% of cases). The most common mode of pleuro-pulmonary involvement is by contiguous spread form liver and occurs in 6% to 40% of cases of amoebic liver abscess (ALA). The abscess may communicate with the tracheo-bronchial tree (hepato-bronchial or broncho-biliary fistula) and in such cases, almost all the pus is expectorated out. A combination of elevated right hemi diaphragm, tender hepatomegaly, right pleural effusion and/or right basal pulmonary lesion should alert the physician to the possibility of thoracic amoebiasis. Combination of metronidazole and drainage usually results in good outcome. Mortality ranges from 5% to 16% and is related to poor general condition, advanced age, malnutrition, delayed diagnosis and inadequate treatment.

23.9 Pulmonary Tuberculosis

MS Jawahar

EPIDEMIOLOGY

Tuberculosis (TB) is a major public health problem, especially in the developing countries of Asia and Africa. Fuelled by the human immunodeficiency virus (HIV) epidemic and the emergence of drug-resistant TB, it poses greater challenges than ever before. Globally two billion people are infected with the TB bacillus. In 2009, there were 9.4 million new cases of TB and 1.68 million deaths. In 2007, there were an estimated 500,000 new cases of multi-drug-resistant TB (MDR-TB) with India, China and the Russian Federation, accounting for more than 50% of such cases. Extensively drug-resistant TB (XDR-TB) has been reported from 58 countries.

In India, more than 40% of the adult population is infected with TB and about 1.9 million people develop TB disease every year. The prevalence is 299 and the mortality 28 per 1,00,000 population, respectively. The HIV infected population in India was estimated to be about 1.8 to 2.9 million in 2007, almost half of whom are also infected with TB and, thus, are at greater risk of breaking down with TB disease.

PATHOGENESIS

TB is transmitted from person to person by the airborne route. The interaction of *Mycobacterium tuberculosis* with the human host begins when droplet nuclei containing micro-organisms from infectious patients are inhaled. While the majority of inhaled bacilli are trapped in the upper airways and expelled by ciliated mucosal cells, a fraction reaches the alveoli where they are phagocytosed by activated alveolar macrophages. The balance between the bactericidal activities of the macrophage and the number and virulence of the bacilli determines the events following phagocytosis.

In the initial stage, either the host's macrophages restrict bacillary multiplication by producing proteolytic enzymes or cytokines, or the bacilli begin to multiply unhindered. If the bacilli multiply, their growth quickly kills the macrophages. Non-activated monocytes attracted by various chemotactic factors ingest the bacilli released from the macrophages.

Soon, two additional host responses develop: a tissue damaging response due to a delayed-type hypersenitivity (DTH) reaction to various bacillary antigens, and a macrophage-activating response which is a cell-mediated phenomenon resulting in the activation of macrophages that are capable of killing and digesting tubercle bacilli. It is the balance between the two that determines the form of TB that will develop subsequently.

With the development of specific immunity and the accumulation of large number of activated macrophages at the site of the primary lesion, granulomatous lesions (tubercles) are formed (**Figure 1**). These consist of lymphocytes and activated macrophages, such as epithelioid cells and Langhans giant cells. Initially, the newly developed tissue-damaging response is the only event capable of limiting mycobacterial growth within the macrophages. This response, mediated by various bacterial products, not only destroys macrophages but also produces solid necrosis in the centre of the tubercle. At this point, some lesions may heal by fibrosis and calcification, while others undergo further evolution.

In the majority of infected individuals, local macrophages are activated when bacillary antigens processed by macrophages stimulate T-lymphocytes to release a variety of lymphokines. These activated cells aggregate around the lesion's centre and effectively neutralise the tubercle bacilli. In the centre of the lesion, the necrotic material resembles soft cheese (caseous necrosis).

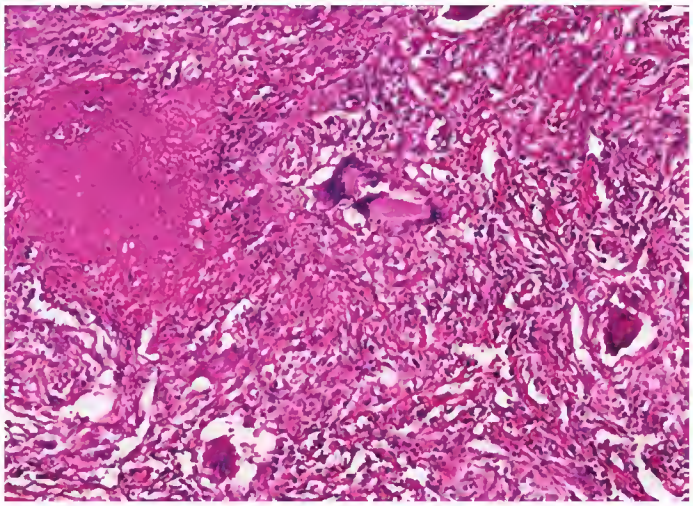

Figure 1: Tuberculous granuloma with caseation, lymphocytes, epithelioid cells, and Langhans giant cells.
Source: http://www.microscopyu.com/galleries/pathology/images/tuberculosis10x02.

In the minority of cases, the macrophage-activating response is weak, and mycobacterial growth can be inhibited only by intensified DTH reactions, which causes tissue destruction. The lesions tend to enlarge and the surrounding tissue is progressively damaged. At the centre of the lesion, the caseous material liquefies. Bronchial walls and blood vessels are invaded and destroyed, and cavities are formed. The liquefied caseous material, containing a large number of bacilli, is drained through bronchi. Within the cavity, tubercle bacilli multiply rapidly and spread into the airways and the environment through expectorated sputum.

In the early stages of infection, bacilli are usually transported by macrophages to regional lymph nodes, from which they disseminate widely to many organs and tissues. The resulting lesions may undergo the same evolution as those in the lungs, although most tend to heal.

Cell-mediated immunity confers partial protection against *M. tuberculosis*, while humoral immunity has no defined role in

protection. Two types of cells are essential: macrophages, which directly phagocytise tubercle bacilli, and T-cells (mainly CD4+ lymphocytes), which induce protection through production of lymphokines, especially interferon gamma (IFN-γ). Coincident with the appearance of immunity, DTH develops. This reactivity is the basis of the tuberculin purified protein derivative (PPD) skin test.

Risk Factors for Development of Clinical TB

A number of factors predispose to the development of TB. These are listed in **Table 1**.

Table 1: Risk Factors for Development of TB

Risk Factors	Relative Risk
HIV infection	100
Jejuno-ileal bypass	30 to 60
Silicosis	30
Post-organ transplantation status	20 to 70
Recent TB infection (< 1 year)	13
Intravenous drug use	10 to 30
Chronic renal failure/haemodialysis	10 to 25
Immunosuppressive/corticosteroid therapy	10
Gastrectomy	2 to 5
Diabetes mellitus	2 to 4
Malnutrition	2

TB = Tuberculosis; HIV = Human immunodeficiency virus.

CLINICAL FEATURES

TB can affect any organ in the body, but primarily the lungs are involved. Pulmonary TB accounts for 85% of all cases of TB. Since the primary mode of transmission of infection is aerial, the initial seeding of the infecting agent occurs in the respiratory tract. Primary infection can result in either a self-healing primary focus, or less frequently lead to progressive pulmonary disease. In a TB endemic country like India, primary infection occurs in childhood, but in a non-endemic setting it can occur at any age.

The predominant symptoms of pulmonary TB are cough, dyspnoea, chest pain and haemoptysis. Chest pain may be due to pleural involvement or of muscular origin due to the strain of chronic cough. Haemoptysis may occasionally be massive due to erosion of bronchial vessels leading to rapid exsanguination. More often the patient has sputum mixed or streaked with blood. In addition, there may be constitutional symptoms, such as fever, night sweats, anorexia, loss of weight and tiredness. Anyone with cough of two weeks or more, chest pain, unexplained fever or haemoptysis should be suspected of pulmonary TB and investigated.

DIAGNOSIS

The diagnosis of pulmonary TB should always include examination of the sputum for acid-fast bacilli (AFB) with Ziehl-Neelsen staining (**Figure 2**). Even though this technique is more than 125 years old, it still remains the cornerstone for the diagnosis of pulmonary TB. It is a simple and cheap test that will detect 50% of cases of pulmonary TB. Every patient with symptoms suggestive of pulmonary TB should have two sputum specimens examined; one spot specimen and one overnight specimen. However, for the sputum to be positive for AFB, it should contain at least 10,000 bacilli per millilitre of sputum. The

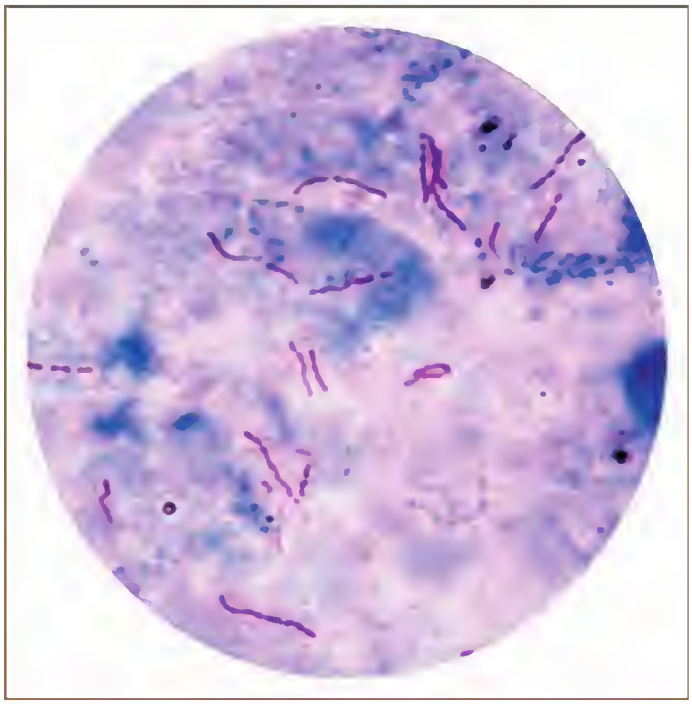

Figure 2: *Tubercle bacilli* viewed with Ziehl-Neelsen staining.

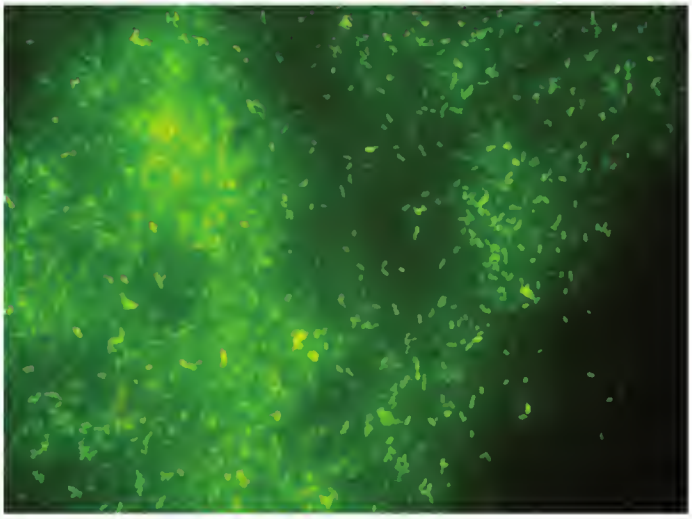

Figure 3: *Tubercle bacilli* viewed under fluorescent microscope.

use of fluorescent microscopy can increase the efficiency of this tool when large numbers of samples are tested (**Figure 3**). Light emitting diode (LED) microscopes are being field tested and may provide cost-effective alternatives in the near future.

When the sputum is less heavily loaded with bacilli, the sputum test may be negative and a chest radiograph may be needed to make the diagnosis (**Figure 4**). Chest radiograph should not be used as the only method of diagnosis for pulmonary TB as it can result in significant over-diagnosis. The interpretation of chest radiographs even by experienced chest physicians is subject to inter- and intra-observer variations. A combination of sputum smear examination and chest radiograph will detect almost all cases of pulmonary TB. It is only rarely that more advanced imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI) will be required.

Sputum culture for TB bacilli is a more sensitive method than sputum smear examination. However, it is expensive, more

Figure 4: Chest radiograph (postero-anterior view) of a patient with bilateral pulmonary tuberculosis showing infiltrative lesions of both upper and right middle lung zones.

labour intensive and it usually take 6 to 10 weeks for the results to be available. Sputum culture is of crucial importance when drug resistance is suspected. Recently, automated liquid culture systems have been developed as alternatives to conventional solid media culture. These systems detect products of bacterial metabolism (carbon dioxide production or oxygen consumption with radiometric sensors—BACTEC 460 TB), fluorescent sensors [BACTEC Mycobacteria Growth Indicator Tube (MGIT) 960], colorimetric sensors (MB/BacT system), pressure sensors (ESP culture system II), or redox reagents, such as Alamar blue. These techniques significantly reduce the time for detection, compared with Lowenstein-Jensen culture. The use of liquid culture media in plates and detection of microcolonies and cord formation by inverted microscopy are also a useful tools that are being field tested. By incorporating anti-TB drugs to the media, this technique (termed microscopic-observation drug-susceptibility assay or MODS) can be used for early detection of drug resistance. Another new tool that is being evaluated is the use of mycobacteriophages (FASTPlaqueTB).

Apart from demonstrating the bacilli or detecting its by-products, indirect methods of diagnosis (such as the detection of antigens associated with *M. tuberculosis* or antibodies against it) are also available, though these tools are more often used in the diagnosis of extra-pulmonary TB. However, none of the existing commercial serological tests show adequate sensitivity and specificity to be recommended for diagnostic use.

Nucleic acid amplification (NAA) techniques, such as polymerase chain reaction (PCR), have also been gaining increasing importance again more for the diagnosis of extra-pulmonary TB. However, their use in diagnosis is limited in TB-endemic settings, primarily because of their cost and complexity. A molecular line probe assay is being evaluated in the field by the TB control programmes for rapid detection of rifampicin and isoniazid resistance and, in combination with liquid culture, is expected to provide timely results of drug resistance. The biggest advantage of this technique is that it can be applied directly to clinical specimens, reducing the delay in the diagnosis of drug resistance considerably.

Rapid species identification of culture isolates can be accomplished by molecular probes or high-performance liquid chromatography (HPLC).

The tuberculin (PPD) skin test detects latent TB infection and should not be used as a diagnostic test for TB disease in adults. Of late, IFN-γ release assays have emerged as an efficient alternative to the skin test. There are 2 promising new *in vitro* tests: QuantiFERON-TB Gold uses a whole-blood assay to measure IFN-γ production from sensitised T-cells, whereas the T-SPOT-TB test uses an enzyme-linked immunospot assay to quantify the number of peripheral blood mononuclear cells producing IFN-γ in response to TB-specific antigen stimulation (early secreted antigenic target 6, ESAT-6, and culture filtrate protein-10 (CFP-10). IFN-γ assays do not differentiate between latent and active TB.

TREATMENT

The aims of treatment of TB are to cure the patient, to prevent morbidity and mortality, to prevent transmission of TB to others, to prevent the development of drug resistance and to prevent relapse of TB. All these are achieved by initiating, and ensuring completion of appropriate anti-mycobacterial therapy as early as possible.

The era of TB chemotherapy began with the discovery of streptomycin by Selman Abraham Waksman in 1944 for which he was awarded the Nobel Prize for Physiology or Medicine in 1952. This was followed by para-aminosalicylic acid (PAS) in 1949 and isoniazid in 1952. The introduction of rifampicin and pyrazinamide in the late 1960s made it feasible to shorten the duration of TB treatment considerably and heralded the era of short-course chemotherapy. Much of the path-breaking researchs for the treatment of TB have come from India, mainly from the Tuberculosis Research Centre (TRC), Chennai, and the National Tuberculosis Institute (NTI), Bangalore, and have helped to define the principles of TB chemotherapy.

Current short-course regimens use an initial intensive phase (usually 2 months) of multiple drugs to rapidly reduce the number of TB bacilli; this is followed by a longer continuation phase of fewer drugs that have the ability to kill the more slowly growing organisms. Thus, the first phase of anti-TB treatment focuses on rapid killing of organisms (bactericidal activity). It takes much longer to kill the more slowly growing organisms or 'persistors', and the goal of this phase of treatment is to reach a point of 'sterilisation' (sterilising activity).

Four drugs, isoniazid, rifampicin, pyrazinamide and ethambutol are considered the first-line drugs for the treatment of TB. These drugs are well absorbed after oral administration and peak blood levels are reached in 2 to 4 hours with near-complete elimination in 24 hours.

The treatment regimen of choice for patients with newly diagnosed TB consists of an initial intensive phase of two months with isoniazid, rifampicin, pyrazinamide and ethambutol followed by a continuation phase of four months

with isoniazid and rifampicin. In settings where the initial isoniazid resistance is high or where drug susceptibility tests (DST) are not done, the World Health Organization (WHO) recommends the addition of ethambutol to the continuation phase (**Tables 2 and 3**). Treatment may be given either daily throughout in the intensive phase followed by thrice weekly in the continuation phase or thrice weekly throughout. There is sufficient evidence from clinical trials to show that intermittent treatment regimens (administered three times a week) are as efficacious as daily regimens in the treatment of TB, while being less expensive, having fewer adverse drug reactions and facilitating directly observed therapy.

Table 2: Treatment Regimens for TB Recommended by the WHO

TB Patient Definition	Treatment Regimen	
	Initial Phase	Continuation Phase
Newly diagnosed TB patients	HRZE for 2 months	HR for 4 months
Newly diagnosed TB patients in settings with high initial isoniazid resistance/ DST not done	HRZE for 2 months	HRE for 4 months
Previously treated sputum smear-positive pulmonary TB	SHRZE for 2 months/HRZE for 1 month	HRE for 5 months

TB = Tuberculosis; WHO = World Heolth Orgonizotion; DST = Drug susceptibility tests; H = Isoniozid; R = Rifompicin; Z = Pyrozinamide; E = Ethombutol; S = Streptomycin.

Table 3: Doses of First-line Anti-TB Drugs for Adults

	Recommended Dose			
	Daily		Three times per week	
	Dose and range (mg/kg body weight)	Maximum (mg)	Dose and Range (mg/kg body weight)	Maximum (mg)
Isoniazid	5 (4 to 6)	300	10 (8 to 12)	900
Rifampicin	10 (8 to 12)	600	10 (8 to 12)	600
Pyrazinamide	25 (20 to 30)	—	35 (30 to 40)	—
Ethambutol	15 (15 to 20)	—	30 (25 to 35)	—
Streptomycin*	15 (12 to18)	—	15 (12 to 18)	1,000

**For potients oged 60 yeors or above ond/or weighing less thon 50 kg-10 mg/kg with maximum of 500-750 mg.*

Tobles 2 ond 3 odapted from: Treotment of Tuberculosis Guidelines, fourth edition, World Health Orgonizotion, 2009, WHO/HTM/TB/2009.420.

For those patients with a history of previous TB therapy, the treatment of choice is determined on the availability of DST results. In the absence of such facility, or while waiting for the results, the patient is treated with an 8-month regimen consisting of isoniazid, rifampicin, pyrazinamide and ethambutol for 3 months with streptomycin for the first 2 months, followed by isoniazid, rifampicin and ethambutol for 5 months (**Tables 2 and 3**). The regimen is modified if the DST shows resistance to isoniazid and rifampicin.

Role of Corticosteroids

Use of corticosteroids is not recommended in the routine treatment of pulmonary TB. However, they are of value in disseminated TB, such as miliary and meningeal TB, and for the management of pericardial and pleural effusions.

Revised National Tuberculosis Control Programme (RNTCP)

The RNTCP has been in operation since the 1990s. It is based on the WHO's global strategy for TB control and emphasises the importance of standardised treatment regimens administered as 'Directly Observed Treatment, Short Course' as one of the important components. The DOTS strategy, which has its origin in India, is today recognised as the cornerstone of efficient TB management. This is a comprehensive strategy and places the responsibility of curing the TB patient on the health provider system.

Under RNTCP, newly diagnosed patients (pulmonary and extra-pulmonary) are treated with a 6-month regimen of isoniazid, rifampicin, pyrazinamide and ethambutol thrice-weekly for 2 months followed by isoniazid and rifampicin thrice-weekly for 4 months. The patient's response to treatment is monitored with sputum smear examination at 2 and 4 months and at the end of treatment. If the second month sputum smear is positive for *M. tuberculosis*, the intensive phase is extended for one more month.

Previously treated TB patients, comprising of relapse, treatment after interruption or treatment failure are treated with an 8-months regimen consisting of isoniazid, rifampicin, pyrazinamide and ethambutol thrice-weekly for 3 months with streptomycin for the first 2 months, followed by isoniazid, rifampicin and ethambutol thrice-weekly for 5 months. In pulmonary TB patients, sputum smear examination is done at the end of the intensive phase, and if it is positive for *Mycobacterium tuberculosis* the intensive phase is extended by one more month. Under RNTCP, newly diagnosed patients (pulmonary and extra-pulmonary) are treated with a 6-month regimen of isoniazid, rifampicin, pyrazinamide and ethambutol thrice-weekly for 2 months followed by isoniazid and rifampicin thrice-weekly for 4 months. The patient's response to treatment is monitored with sputum smear examination at 2 and 4 months and at the end of treatment. If the second month sputum smear is positive for *M. tuberculosis*, the intensive phase is extended for one more month.

During the intensive phase of treatment, every dose is administered under direct observation, while during the continuation phase patients are asked to attend the treatment clinic once a week, when one dose is given under direct observation and the other two doses supplied to the patient for self-administration. A unique feature of the RNTCP is that each patient is allotted a box of medicines that contains drugs for the full duration of the treatment.

COMPLICATIONS

Pulmonary TB that is not adequately and appropriately treated can lead to many complications (**Table 4**), the most important of which is drug resistance. The emergence of MDR-TB and XDR-TB are posing fresh challenges to the global control of this disease.

MDR-TB and XDR-TB

Drug resistance in TB may be either primary (in a patient who has never been exposed to anti-TB drugs) or acquired. Acquired drug resistance is the consequence of inappropriate or irregular therapy. While resistance to a single drug is usually of no major consequence as the resistant bacilli will be killed by the other

Table 4: Complications of Pulmonary Tuberculosis (TB)

Pulmonary	Extra-pulmonary
Development of MDR-TB or XDR-TB	Disseminated TB
Miliary TB	Spread to extra-pulmonary sites, viz. central nervous system and meninges, bones and joints, lymph nodes, genitourinary system, gastrointestinal system, pericardium, skin
Massive haemoptysis	
Cor pulmonale	
Emphysema	
Chronic bronchitis	
Bronchiectasis	
Broncho-pleural fistula	Empyema necessitans
Lung/Pleural calcification	Laryngitis
Aspergilloma	Anorectal disease
Atypical mycobacterial infection	Amyloidosis
	Poncet's polyarthritis

drugs used in the multi-drug treatment regimen, resistance to multiple drugs has major therapeutic implications. MDR-TB is defined as TB caused by bacilli that are resistant to isoniazid and rifampicin, the 2 most potent first-line anti-TB drugs with or without resistance to other drugs. XDR-TB is TB caused by bacilli that are resistant to isoniazid, rifampicin, and also to any of the quinolone group of drugs and any of the injectable second-line drugs, viz. kanamycin, capreomycin or amikacin.

The diagnosis of MDR-TB is a bacteriological diagnosis. Sputum culture and DST should be used to confirm the diagnosis. Incorrect DST results can lead to unnecessary changes of regimen, thus, decreasing the chances of cure.

Treatment of MDR-TB is less effective, more toxic and much more expensive compared to that of drug-susceptible TB. The treatment regimen should include at least four drugs that the patient is known to be susceptible to, or has not previously been exposed to, including an injectable agent and a fluoroquinolone in the initial phase, and at least four of the most active and best-tolerated drugs in the continuation phase. Treatment should be given daily and directly observed. An initial intensive phase of at least 6 months should be followed by a continuation phase of at least 18 months. Treatment should be continued till the sputum cultures remain consistently negative for at least 12 months. The RNTCP now offers a DOTS Plus regimen for patients with MDR TB (**Table 5**). In the initial stages of the treatment, patient should be hospitalised for monitoring treatment and adverse drug reactions. Response to treatment should be monitored with periodic sputum tests. The management of XDR-TB is even more problematical as the choice of effective drugs is severely limited. The treatment regimen should be designed based on the DST results. A treatment regimen using seven drugs (capreomycin, moxifloxacin, cycloserine, ethionamide, ethambutol, pyrazinamide and linezolid) has been recommended.

Pulmonary TB in the HIV Infected Patients

HIV infection is the biggest risk factor for the development of TB. TB can occur at any stage of HIV disease, and its manifestations depend on the level of immunosuppression.

In the early stages of HIV disease, the lungs are most commonly affected, while in the later stages of immunosuppression, extra-pulmonary sites are more often involved. The management of TB in the presence of co-existing HIV infection is challenging. The symptoms of pulmonary TB and other HIV-related respiratory diseases can be very similar. The diagnosis is often more difficult with a greater proportion of smear-negative and extra-pulmonary TB. Radiographic findings may be atypical and may include lower lobe infiltrates and miliary distribution, and cavitary disease may be less likely. While TB patients with concomitant HIV infection may respond as well to standard anti-TB treatment as those who are immunocompetent, deaths during treatment, partly due to HIV itself and partly due to other HIV-related diseases are more frequent. It is also likely that relapse of TB may be higher in HIV-TB patients compared to immunocompetent TB patients.

The combination of anti-retroviral treatment (ART) with anti-TB treatment also presents problems. Apart from the pill burden,

Table 5: Treatment Regimen for MDR-TB Under DOTS Plus of RNTCP

Body Weight (Kg)	Intensive Phase			Continuation Phase		
	Drugs	Dose (mg)	Duration	Drugs	Dose (mg)	Duration
16 to 25	Kanamycin Pyrazinamide Levofloxacin Ethambutol Ethionamide Cycloserine	500 500 500 400 375 250	6 to 9 months	Levofloxacin Ethambutol Ethionamide Cycloserine	500 400 375 250	18 months
26 to 45	Pyridoxine Kanamycin Pyrazinamide Levofloxacin Ethambutol Ethionamide Cycloserine	50 500 1250 750 800 500 500	6 to 9 months	Levofloxacin Ethambutol Ethionamide Cycloserine	750 800 500 500	18 months
>45	Kanamycin Pyrazinamide Levofloxacin Ethambutol Ethionamide Cycloserine	750 1500 750 1000 750 750	6 to 9 months	Levofloxacin Ethambutol Ethionamide Cycloserine	750 1000 750 750	18 months

MDR = Multidrug-resistant; TB = Tuberculosis; DOTS = Directly Observed Treatment Short-course; RNTCP = Revised National Tuberculosis Control programme.

a major handicap is that rifampicin cannot be used along with protease inhibitors. Possible options include deferring anti-retroviral treatment till TB treatment is completed, or at least till the end of the intensive phase of treatment and then to use ethambutol and isoniazid in the continuation phase. If available, rifabutin can be used instead of rifampicin.

Side Effects to Anti-TB Therapy

The adverse effects of anti-TB drugs and their management are described in **Table 6**. These are classified as major or minor. A patient who develops minor adverse effects should continue the TB treatment along with symptomatic treatment. In case of major side effects, the treatment or the responsible drug is stopped, either temporarily or permanently. Patients with major adverse reactions should be managed in a hospital.

with chills and rigours and intense myalgia which typically comes on one to two hours after drug administration. In its milder form it can be managed with antipyretics, but more severe manifestations will warrant the withdrawal of rifampicin from the treatment regimen.

Pregnancy and Breastfeeding

Women of child-bearing age should be advised contraception before starting TB treatment. With the exception of streptomycin, the first line anti-TB drugs are safe for use in pregnancy: streptomycin is ototoxic to the foetus and should not be used during pregnancy. A breast-feeding woman who has TB should receive a full course of TB treatment. Mother and baby should stay together and the baby should continue to breastfeed. After active TB in the baby is ruled out, the baby should be given 6 months of isoniazid preventive therapy, followed by BCG (Bacille Calmette-Guérin) vaccination. Pyridoxine supplementation is recommended for all pregnant or breastfeeding women taking isoniazid.

Table 6: Side Effects to Anti-TB Drugs—Syndrome Based Approach to Management

Side Effects	Drugs Probably Responsible	Management
Minor		Continue anti-TB drugs
Orange or red coloured urine	Rifampicin	Reassurance
Anorexia, nausea, abdominal pain	Pyrazinamide, rifampicin	Give drugs with a small meal or at bed-time
Arthralgia	Pyrazinamide	Aspirin
Itching	Streptomycin, isoniazid, rifampicin, pyrazinamide	Anti-histamines
Burning, numbness or tingling sensation in the hands or feet	Isoniazid	Pyridoxine 50 to 75 mg/dL
Major		Stop responsible drug
Skin rash	Streptomycin, isoniazid, rifampicin, pyrazinamide	Stop streptomycin, isoniazid, rifampicin, pyrazinamide. Try to identify offending drug by challenging with small doses. Re-introduce other drugs
Deafness, dizziness	Streptomycin	Stop streptomycin. Use ethambutol
Jaundice, hepatitis	Isoniazid, rifampicin, pyrazinamide	Stop isoniazid, rifampicin, pyrazinamide. Use streptomycin and ethambutol. Monitor liver function tests (LFTs). Re-introduce isoniazid, rifampicin, pyrazinamide after LFTs become normal
Visual impairment	Ethambutol	Stop ethambutol
Flu syndrome	Rifampicin	Stop rifampicin
Acute renal failure	Rifampicin	Stop rifampicin
Thrombocytopenia	Rifampicin	Stop rifampicin
Shock	Rifampicin	Stop rifampicin

Adapted from: Treatment of Tuberculosis Guidelines, fourth edition, World Health Organization, 2009, WHO/HTM/TB/2009.420.

The most common of the major adverse reactions is hepatitis and jaundice. Rifampicin induces hepatic enzymes and a transient elevation of the enzymes acetyl aminotransferase (AST) and alanine aminotransferase (ALT) are expected. If this is accompanied by elevated serum bilirubin, hepatotoxic anti-TB drugs (isoniazid, rifampicin and pyrazinamide) should be temporarily withheld and the patient treated with streptomycin and ethambutol. Once the liver function becomes normal, the original regimen may be resumed. Acute renal failure and acute thrombocytopenia warrant the stopping of rifampicin, which should then not be used again in these patients. Flu syndrome is a rare phenomenon usually associated with intermittent rifampicin usage (twice or thrice weekly) and manifests as fever

23.10 Fungal Infections of Lungs

Ashok Shah

INTRODUCTION

Fungal pneumonias are common nosocomial infections in the immunocompromised host and are often associated with a high morbidity and mortality (**Table 1**). The global human immunodeficiency virus (HIV) epidemic, increased organ transplantation and immunosuppressant use have contributed to the increased occurrence of fungal infections of the lungs. Community-acquired pulmonary fungal infections are also seen, especially in those with pre-existing lung ailments.

Table 1: Classification of Fungal Infections of the Lungs

Allergic
Allergic bronchopulmonary mycoses
Allergic fungal sinusitis
Immunoglobulin (Ig)-E mediated asthma
Bronchocentric granulomatosis
Hypersensitivity pneumonitis
Chronic eosinophilic pneumonia
Saprophytic infestation of airways, cavities and necrotic tissue
Fungal ball, e.g. aspergilloma
Semi-invasive
Chronic necrotising fungosis
Invasive
Acute (necrotising) bronchopneumonia
Tracheobronchitis
Obstructive
Pseudomembranous
Ulcerative
Invasive pleural disease (fungal empyema)

EPIDEMIOLOGY

The aetiologic agents of respiratory mycoses range from yeast-like to dimorphic and filamentous fungi and can be divided into two groups, namely, opportunistic and endemic. The opportunistic fungi are normally commensals but cause disease in an immunocompromised state. These include *Candida* species, *Aspergillus* species, *Cryptococcus neoformans*, and the zygomycetes (*Mucor*, *Rhizopus*). Fungi, previously thought to be non-pathogenic or only sporadically associated with human disease, such as *Candida* (except *C. albicans*), *Fusarium*, *Trichosporon*, and *Malassezia* species, are now emerging as important nosocomial fungal pathogens. The opportunistic fungi have a cosmopolitan distribution and are commonly detected either in immunosuppressed patients or those who are critically ill.

Endemic fungi, on the other hand, are those that can cause disease in normal hosts as well. They are usually restricted in distribution to discrete geographic regions. These are *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, sporotrichosis, and penicilliosis. Pulmonary fungal infections common in India are aspergillosis, cryptococcosis, histoplasmosis, blastomycosis and zygomycosis.

The data on worldwide incidence and prevalence of pulmonary fungal infections are scanty. It was reported that up to 7% patients dying in hospitals have invasive aspergillosis. *Candida* species accounts for 8% to 15% of nosocomial blood stream infections, and are the fourth most common isolate of patients in the intensive care unit (ICU). *Candida* colonisation has also been seen in respiratory samples obtained by bronchoalveolar lavage (BAL), endotracheal aspirate, or protected brush catheter specimens in critically ill non-neutropenic patients. Among the specific patient groups, about 15% of allogenic haemopoietic stem cell transplant recipients develop fungal pneumonia. Approximately 60% and 20% of patients with acquired immunodeficiency syndrome (AIDS) admitted to ICU have *Pneumocystis jirovecii* pneumonia or oesophageal candidiasis, respectively. *Penicillium marneffei* infections are seen in about 30% of people with AIDS in South-East Asia including north-eastern states of India. Endemic fungal infections are commoner in men since oestrogen inhibits transformation of mycelium to the yeast form.

RISK FACTORS

A number of factors may be associated with an increasing incidence of pulmonary fungal infections (**Table 2**). Nosocomial *Aspergillus* species outbreaks have been related to contaminated air or ventilation systems. Recently, many cases of fungal pneumonias have been reported in patients with chronic obstructive pulmonary disease (COPD).

Table 2: Risk Factors for Fungal Pneumonia

Acute leukaemia or lymphoma during myeloablative chemotherapy
Bone marrow transplantation
Solid organ transplantation on immunosuppressive treatment
Prolonged corticosteroid therapy
Acquired immunodeficiency syndrome
Congenital immune deficiency syndromes
Antimicrobial agents and chemotherapy
Presence of indwelling intravascular catheters
Endotracheal tubes and urinary catheters
Neutropenia, in particular associated with fever
Prior haemodialysis
Previous fungal colonisation

CLINICAL PRESENTATION

Acute Pneumonia

In individuals who are neutropenic or immunocompromised, persistent fever (even before the onset of pulmonary findings) may be an early sign of infection. Cough is usually dry, and is associated with pleuritic chest pain. Breathlessness may be marked and respiratory failure may be present. Haemoptysis is seen in patients with invasive aspergillosis or mucormycosis.

Tracheobronchitis

Tracheobronchitis has only been reported with *Aspergillus* species. *Aspergillus* tracheobronchitis is classified into three forms, namely, obstructive, pseudomembranous and ulcerative. Obstructive tracheobronchitis is characterised by thick mucous

plugs full of *Aspergillus* species without macroscopic evidence of bronchial inflammation. The pseudomembranous form typically shows extensive inflammation of the tracheobronchial tree, with a membrane overlying the mucosa containing *Aspergillus* species. The term ulcerative *Aspergillus* tracheobronchitis (UATB) is reserved for patients with limited involvement of the tracheobronchial tree. Patients with UATB have a favourable outcome in lung transplant patients due to surveillance bronchoscopy and prompt initiation of antifungal therapy in the post-transplantation course.

INFECTIONS CAUSED BY YEAST-LIKE FUNGI AND *CANDIDA*

Fungi isolated from sputum may either be commensals, pathogens or saprophytes. Primary *Candida* pneumonia refers to invasive infections limited to the lungs. Secondary *Candida* pneumonia refers to lung involvement due to haematogenous dissemination. The diagnosis of *Candida* pneumonia can be firmly established only on histopathology. This entity, while often documented at autopsy, is usually masked completely by the other manifestations of invasive candidiasis. Classical findings of secondary *Candida* pneumonia are microabscesses with pseudohyphae penetrating blood vessels, lung interstitium and airways.

Aspergillus Infections

Aspergillus species constitute the second most common cause of hospital-acquired fungal infections after *Candida*. It may be seen in up to 30% of patients with haematological malignancies. Lung involvement due to *Aspergillus* species ranges from saprophytic colonisation (aspergilloma) to rapidly invasive and disseminated disease. Allergic bronchopulmonary aspergillosis (ABPA) is the most frequently recognised manifestation of *Aspergillus* associated hypersensitivity respiratory disorder. On histopathology, fungal hyphae can be observed in invasive pulmonary aspergillosis (**Figure 1**).

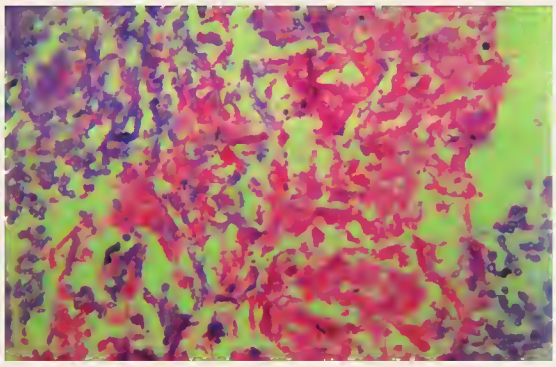

Figure 1: Photomicrograph showing filaments of *Aspergillus* in a patient with invasive pulmonary aspergillosis Haematoxylin, ×40.
Courtesy: Dr Sudhir Jain.

DIAGNOSIS

Diagnosis of pulmonary mycoses is often difficult due to lack of specific pathognomonic clinical syndrome and characteristic radiological features. In our country, the problem is further confounded by lack of dedicated diagnostic mycology laboratories. Patients with pulmonary mycoses are often misdiagnosed as tuberculosis, bacterial diseases, flu-like infections, or any disease of obscure aetiology and thus suffer the complications of unwarranted chemotherapy and/or surgery.

Opportunistic infections should be suspected in patients presenting with leucopenia and/or neutropenia. However, leucocytosis (endemic mycoses), eosinophilia (coccidioidomycosis) may sometimes be encountered. Culture of respiratory tract secretions is crucial to the diagnosis.

Fibre-optic bronchoscopy is useful to obtain samples for smear examination and cultures. Transbronchial lung biopsy is useful for detecting tissue invasion. Bone marrow aspiration and/or biopsy, smear and culture of other specimens like blood, urine, and cerebrospinal fluid are also useful diagnostic aids. A urine fungal culture in men after a prostatic massage helps to identify *Cryptococcus* species.

Serologic tests facilitate rapid diagnosis of fungal infections. Antigen detection using enzyme-linked immunosorbent assay (ELISA) or latex agglutination and molecular methods like polymerase chain reaction are useful in detecting *Candida* species and *Histoplasma capsulatum*. Detection of *Histoplasma* antigen in urine or serum is useful in diagnosis and to evaluate the efficacy of treatment in disseminated histoplasmosis. In invasive *Aspergillus* pneumonia, galactomannan ELISA may be positive in the blood very early, prior to clinical suspicion of invasive fungal infection. On histopathology, caseating or necrotising granulomas with intracellular organisms inside macrophages are seen in infections with *Histoplasma capsulatum* or *Coccidioides immitis*.

Consolidation, nodular shadows, patchy infiltrates, cavitating lesions and pleural effusion are the common findings on the chest radiograph. Mediastinal adenopathy is seen in patients with endemic fungal pneumonias. Miliary mottling may occur in patients with disseminated disease. Computed tomography (CT) scan is useful in the evaluation of non-specific infiltrates in immunocompromised patients. The 'halo sign' on CT is now regarded as an early indicator of invasive pulmonary aspergillosis. A nodular core is present but there is no visible pulmonary parenchyma. This is surrounded by a ground-glass perimeter, through which pulmonary parenchyma is visible. Macronodules including 'infarct-shaped nodules', 'crescent sign' along with cavitation (**Figure 2**) and consolidation may also be seen. An algorithm showing approach to diagnosis is depicted in **Figure 3**.

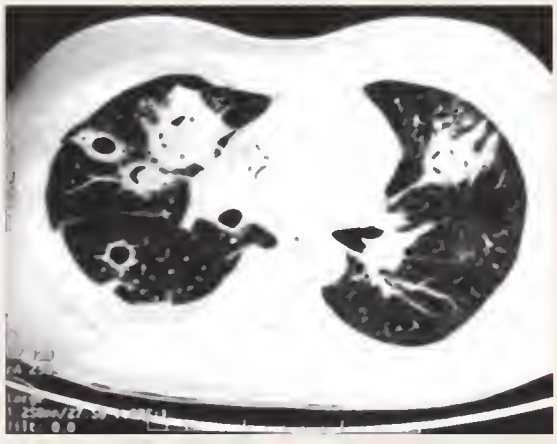

Figure 2: Computed tomography of the thorax showing bilateral 'macronodules' along with a 'crescent sign' on the right side in a patient with invasive pulmonary aspergillosis. An 'infarct-shaped nodule' abutting the pleural surface on the right side is also visible
Courtesy: Dr Puneet Khanna.

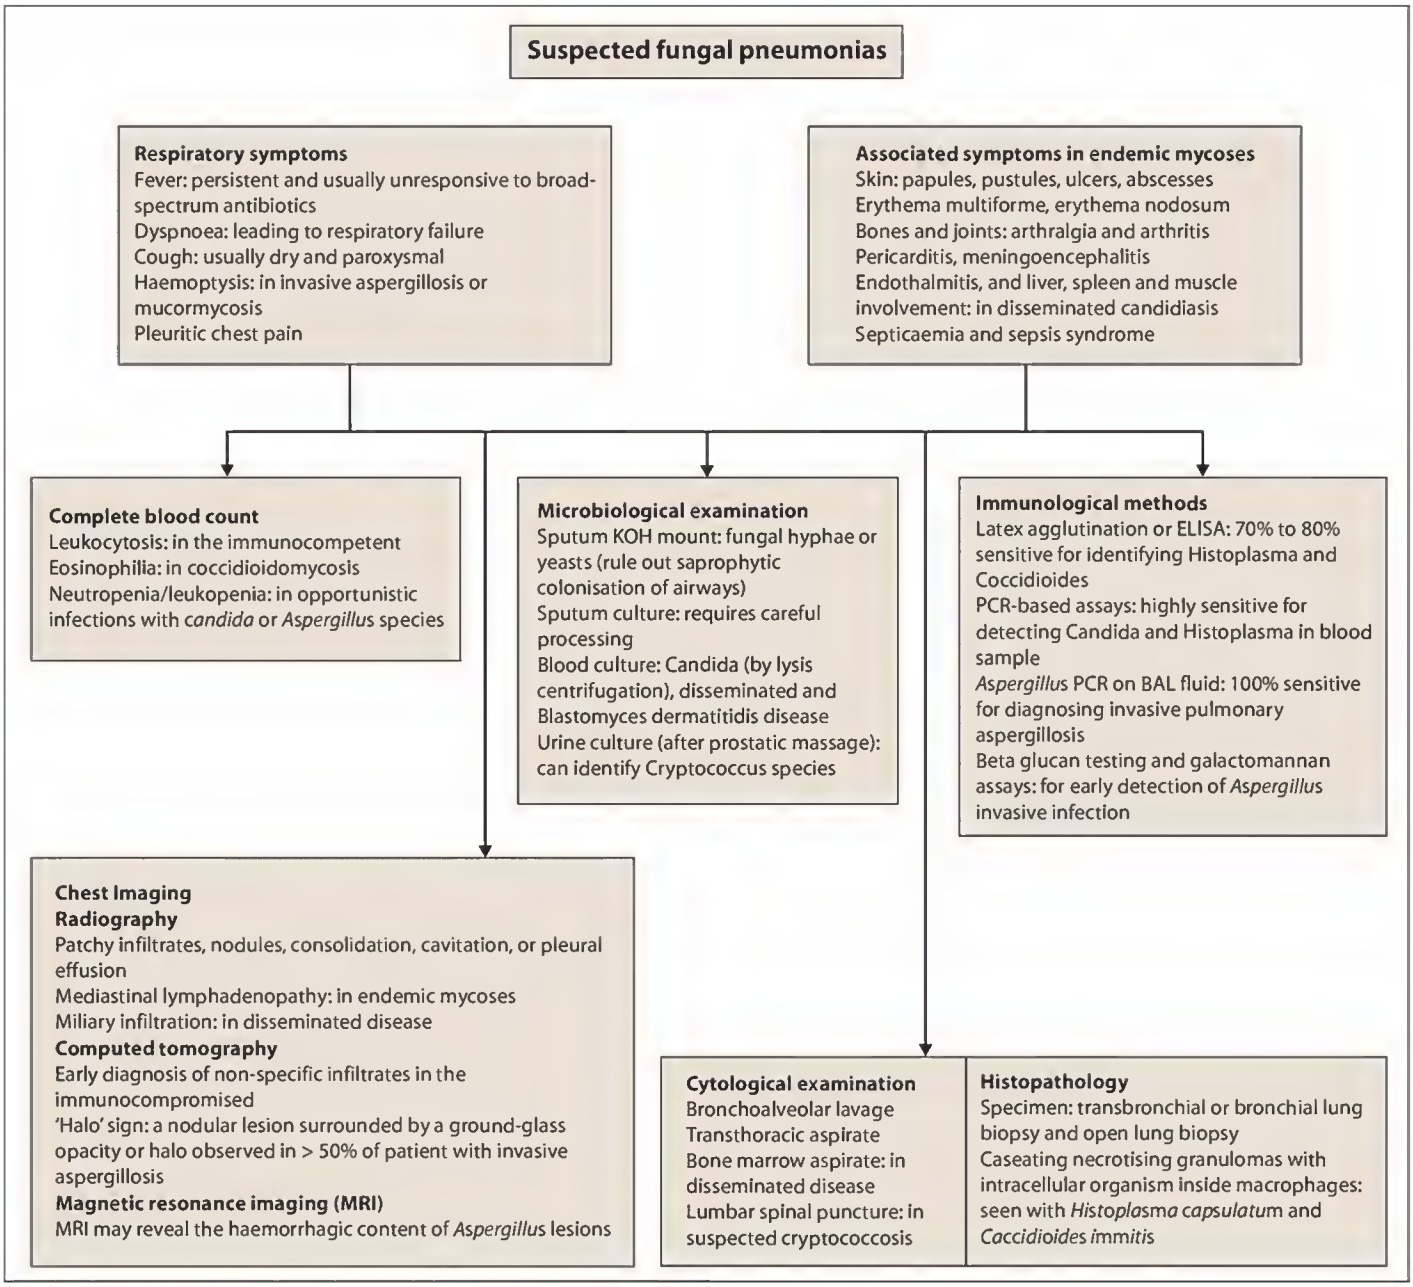

Figure 3: Diagnostic algorithm for patients with suspected fungal pneumonias.

KOH = Potassium hydroxide; ELISA = Enzyme-linked immunosorbent assay; PCR = Polymerase chain reaction; BAL = Bronchoalveolar lavage.

TREATMENT

Spontaneous recovery without treatment usually occurs in endemic mycoses, especially in mildly affected immunocompetent patients. However, early institution of treatment, even when diagnostic tests are underway, is required if dissemination occurs. Antifungal agents (**Table 3**) are the mainstay of the treatment. Due to improved survival rates, as demonstrated in randomised controlled trials, voriconazole is the drug of choice for primary treatment of invasive pulmonary aspergillosis. The recommended duration of therapy is at least 6 to 12 weeks. In immunocompromised patients, it is better to continue antifungal agents throughout the entire period of immune suppression and also until the lesions have resolved. During subsequent immunosuppression, empirical treatment may be of help in the prevention of infection.

Reversing the factors responsible for the immunocompromised state may facilitate successful recovery. In patients with candidiasis, it is important to remove indwelling infected intravenous lines or urinary catheters, especially in the setting of haematogenous spread. Furthermore, rapid tapering of immunosuppressants and corticosteroids should be achieved, lest relentless infection might ensue. Usage of growth factors is helpful in patients with febrile neutropenia. In patients with coccidioidomycosis and mucormycosis, surgical debridement or resection of necrotic tissue is often a necessary adjunct to antifungal treatment. Surgery may also be useful in haemoptysis from a single focus, lesions contiguous with the great vessels or pericardium, and invasion of the chest wall. Another relative indication for surgery is the resection of a single pulmonary lesion prior to intensive chemotherapy.

Table 3: Antifungal Agents Used in the Treatment of Respiratory Mycoses

Drug	Mode of Action	Indications
Flucytosine	Acts directly on fungal organisms by competitive inhibition of purine and pyrimidine uptake and indirectly by intracellular metabolism to 5-fluorouracil after penetrating fungal cells. Inhibits RNA and protein synthesis	Active against *Candida* and *Cryptococcus* species Generally used in combination with amphotericin B
Fluconazole	Selectively inhibits fungal CYP450 and sterol C-14 alpha demethylation	Candidiasis, coccidioidomycosis, blastomycosis/histoplasmosis Maintenance therapy in patients with AIDS and cryptococcal meningitis or recurrent oropharyngeal candidiasis
Itraconazole	Slows fungal cell growth by inhibiting CYP450 dependent synthesis of ergosterol, a vital component of fungal cell membranes	Fungistatic activity demonstrated against disseminated fungal infections caused by *Blastomyces dermatitidis, Histoplasma duboisii, Aspergillus fumigatus, Cryptococcus immitis, Cryptococcus neoformans, Paracoccidioides brasiliensis, Sporothrix schenckii, Trichophyton rubrum*, and *Trichophyton mentagrophytes* Patients with pulmonary and extra-pulmonary aspergillosis who are intolerant of or are refractory to amphotericin B therapy
Voriconazole	Inhibits fungal CYP450 mediated 14 alpha-lanosterol demethylation, which is essential in fungal ergosterol biosynthesis	Primary treatment of invasive aspergillosis Initial therapy for tracheobronchitis Salvage treatment of *Fusarium* species or *Scedosporium apiospermum* infections
Amphotericin B	Exerts antifungal activity, principally by binding to sterols in the fungal cell membrane	Broad spectrum of activity against pathogenic fungi, including yeasts, except *Fusarium* species
Caspofungin	Inhibits synthesis of beta-(1,3)-D-glucan, an essential component of fungal cell wall	Refractory invasive aspergillosis and salvage therapy
Anidulafungin	Inhibits synthesis of beta-(1,3)-D-glucan, an essential component of fungal cell wall	Invasive candidiasis
Micafungin	Inhibits synthesis of beta-(1,3)-D-glucan, an essential component of fungal cell wall	Candidemia, acute disseminated candidiasis

CYP450 = Cytochrome P-450; RNA = Ribonucleic acid; AIDS = Acquired immunodeficiency syndrome.

The principles of management of fungal pneumonias are described in **Table 4**.

As in invasive fungal pneumonias, early institution of treatment for *Aspergillus* tracheobronchitis may help in (i) preventing anastomotic disruptions in lung transplant recipients, and (ii) clearing off ulcerative tracheobronchial lesions. Here too, voriconazole is the drug of choice. The role of aerosolised amphotericin is under investigation. The dosage regimens with various antifungal agents is given in **Tables 5 A to C**.

COMPLICATIONS

Dissemination to other sites and sepsis syndrome are the most common complications of fungal pneumonias. Blood vessel invasion can lead to haemoptysis, pulmonary infarction, myocardial infarction, cerebral emboli, cerebral infarction, or blindness. Fibrosing mediastinitis and broncholithiasis are commonly observed in histoplasmosis. Other complications include bronchopleural or tracheoesophageal fistulas, pericarditis and arthritis.

Table 4: Principles of Management of Fungal Pneumonias

Aetiological Cause	Antifungal Drugs
Candidiasis	Amphotericin B is the mainstay of treatment. Flucytosine may be of benefit when added to amphotericin B Fluconazole use in pulmonary disease not studied but is effective in hepatosplenic candidiasis and candidemia. Anidulafungin is useful in invasive disease
Aspergillosis, Zygomycoses	Amphotericin B is often started empirically in patients who are neutropenic with fever and unexplained pulmonary infiltrates and cannot tolerate an invasive pulmonary procedures. Flucytosine is synergistic with amphotericin B. Rifampicin often added empirically when patient is deteriorating in face of amphotericin B. Itraconazole used to complete the treatment with initial response to amphotericin B; *Mucor* species generally resistant to azoles. Ketoconazole may be antagonistic with amphotericin B
Cryptococcosis	Amphotericin B in patients who are severely ill. Fluconazole in milder cases or after clinical response to amphotericin B. Lifelong maintenance therapy in AIDS due to frequent recurrences when treatment is stopped
Histoplasmosis	Amphotericin B induces rapid response in patients who are severely ill Azoles/triazoles in patients with milder illness
Coccidioidomycosis	Amphotericin B is effective in more than 90% of cases Fluconazole or itraconazole after improvement. Treatment is less effective than in other endemic mycoses

Table 5A: Dosing of Antifungal Agents: Azoles

Fluconazole	
Systemic candidiasis	400 mg po/IV qid; continue for a minimum of 4 weeks and for at least 2 weeks after symptoms resolve
Coccidioidomycosis	400 mg po/IV for 1 day, then 200 to 400 mg po/IVmg; 400 to 800 mg po/IV for patients infected with AIDS
Blastomycosis	400 to 800 mg po/IV
Histoplasmosis	400 to 800 mg po/IV
Itraconazole	
Aspergillosis	200 to 400 mg po for 1 year
Blastomycosis	200 to 400 mg po for 6 months
Coccidioidomycosis	200 mg po bid for 12 to 18 months
Histoplasmosis	Moderate: 200 mg po for 9 months
	Life-threatening: 200 mg po tid for 3 days, then, 200 mg po bid until response
Patients with HIV	400 mg po for 12 weeks (85 to 90% response); then 200 mg po
Paracoccidioidomycosis	200 mg po qd for 6 months
Recommended IV dose	200 mg IV bid for 4 doses, then 200 mg IV for maximum of 14 days (each dose infused over 1 hour)
Voriconazole	
Loading dose	6 mg/kg IV q12 hours infused over 2 hours for 2 doses
Maintenance	4 mg/kg IV q12 hours infused over 2 hours; when able to tolerate po, may switch to 200 mg po q12 hours

Table 5B: Dosing of Antifungal Agents: Amphotericin B

Conventional	0.25 to 1.5 mg/kg per day IV; not to exceed 1.5 mg/kg per day
Test dose	1 mg in 20 mL of D5W infused IV over 20 to 30 min; monitor pulse, respiration rate, temperature and blood pressure q30min for 2 hours
Invasive aspergillosis	0.5 to 0.6 mg/kg per day IV (1 to 1.5 mg/kg per day in patients who are neutropenic for rapidly progressing, potentially fatal infections); cumulative dose of 1.5 to 4 g has been administered over 11 months
Mucormycosis	1 to 1.5 mg/kg per day IV for 2 to 3 months; cumulative dose of 3 to 4 g
Invasive candidiasis	0.4 to 0.6 mg/kg per day IV (1 to 1.5 mg/kg per day for candidemia or rapidly progressing potentially fatal infections); treat for 7 to 14 days in low-risk patients (6 weeks or longer in high-risk patients)
Blastomycosis	0.5 to 1 mg/kg per day IV; cumulative dose of 1.5 g
Coccidioidomycosis	0.5 to 1 mg/kg per day IV (1.5 mg/kg per day in rapidly progressing, potentially fatal infections); treat for 4 to 12 weeks
Histoplasmosis	0.5 to 1 mg/kg per day IV for 7 days; then 0.8 mg/kg IV
Paracoccidioidomycosis	0.4 to 0.5 mg/kg per day IV; total dose of 1.5 to 2.5 g
Cryptococcosis	0.3 to 1 mg/kg per day IV (with or without flucytosine) until response, usually 2 to 4 weeks to several months; then change to fluconazole 400 mg po/IV for 8 to 10 weeks; in patients with HIV infection, follow with indefinite treatment with fluconazole at 200 mg per day
Lipid complex	5 mg/kg per day for aspergillosis at median duration of 25 days; as long as 6 weeks for cryptococcosis in patients with HIV infection; then, 12 week of fluconazole po
Liposomal amphotericin B	3 to 5 mg/kg per day IV for systemic fungal infections (e.g., *Aspergillus*, *Candida*, and *Cryptococcus* species)

Table 5C: Dosing of Antifungal Agents: Echinocandins

Caspofungin	70 mg IV over 1 hour on day 1; 50 mg IV thereafter
Anidulafungin	
Candidemia/candidiasis	200 mg IV on day 1; decrease dose on day 2 and thereafter to 100 mg/d IV; do not exceed infusion rate of 1.1 mg/min
Micafungin	
Candidemia and *Candida* peritonitis/abscesses	100 mg IV once daily
Oesophageal candidiasis	150 mg IV once daily

PROGNOSIS

Disseminated invasive fungal infections of the lungs are associated with a high mortality, often exceeding 80%. The individual prognosis ultimately is linked with the severity and outcome of the underlying disease, and to whether the reversal of factors affecting the patient's immune status is possible.

23.11 Diffuse Interstitial Lung Disease

SK Jindal

INTRODUCTION

Diffuse interstitial lung disease (ILD) encompasses a group of disorders of diverse aetiologies with common feature of generalised involvement of the lung interstitium. It includes over 200 different diseases which, in spite of their heterogenous nature have several common clinical, radiological and histological manifestations.

AETIOLOGY AND CLASSIFICATION

Interstitial lung disease is broadly grouped as: (1) primary, when the cause is unknown; and (2) secondary, when there is an identifiable disease responsible for the interstitial involvement (**Table 1**).

Table 1: Important Causes of Interstitial Lung Disease

Primary or idiopathic
- Idiopathic pulmonary fibrosis (IPF) or usual interstitial pneumonia (UIP)
- Non-Specific interstitial pneumonia (NSIP)
- Organising pneumonia (OP)
- Respiratory bronchiolitis (RB)
- Diffuse alveolar damage (DAD)
- Desquamative interstitial pneumonia (DIP)
- Lymphocytic interstitial pneumonia (LIP)

Association with diseases of known aetiology
- Infections
  - Tuberculosis
  - Bacterial
  - Fungal
  - Parasitic
  - Viral
- Non-infectious causes
  - Hypersensitivity pneumonitis
  - Pneumoconioses
  - Drug-induced
  - Radiation-induced
  - Malignancies
  - Systemic vasculitides

Association with diseases of unknown aetiology
- Sarcoidosis
- Connective tissue disorders
- Systemic sclerosis
- Rheumatoid arthritis
- Polymyositis-dermatomyositis
- Systemic lupus erythematosus
- Chronic eosinophilic pneumonia

Miscellaneous
- Histiocytosis X
- Eosinophilic granuloma
- Lymphangioleiomyomatosis
- Tuberous sclerosis

Primary Interstitial Lung Disease

Primary ILD is idiopathic in origin. No secondary cause or association is identifiable. It was also known in the past as cryptogenic fibrosing alveolitis or idiopathic pulmonary fibrosis (IPF) or 'lone IPF'. This group of idiopathic interstitial pneumonias (IIPs) based on clinico-radiological and pathological features, is now classified into seven distinct types: (1) usual interstitial pneumonia (UIP), (2) desquamative interstitial pneumonia (DIP), (3) lymphocytic interstitial pneumonia (LIP), (4) non-specific interstitial pneumonia (NSIP), (5) acute interstitial pneumonia (AIP), (6) diffuse alveolar damage (DAD) and (7) cryptogenic organising pneumonia (COP). Some of these IIPs such as the DIP, NSIP and respiratory bronchiolitis associated ILD (RBILD) are characteristically associated with the smoking history.

Secondary Interstitial Lung Diseases

Most forms of secondary ILDs have either a known aetiological cause or an association with another disease of known (or unknown) aetiology. An ILD secondary to another illness factually represents the pulmonary involvement of the primary disease than a separate entity.

The most important association of ILD is seen with different connective tissue disorders (CTDs). Progressive systemic sclerosis (PSS) and rheumatoid arthritis (RA) are frequent causes. Systemic lupus erythematosus (SLE), polymyositis-dermatomyositis syndrome and ankylosing spondylitis are also known to cause pulmonary fibrosis. There is a great degree of overlap between IPF and fibrosis associated with different connective tissue disorders.

Occupational exposure to different inorganic and metal dusts is another important cause. Silica dust causes progressive fibrosis, massive progressive fibrosis can occur in such a short period of few weeks to a few months in case of a heavy exposure. Asbestosis and anthracosis are also associated with pulmonary fibrosis.

Sarcoidosis as a cause of ILD, is now commonly recognised. Interstitial involvement occurs in stage II sarcoidosis along with the presence of hilar and mediastinal lymphadenopathy. It can also occur alone in the absence of lymph node enlargement (stage III sarcoidosis).

Several drugs are known to cause ILDs. The list includes most of the cytotoxic drugs (bleomycin, mitomycin, busulfan, cyclophosphamide, methotrexate and BCNU) and several non-cytotoxic drugs (such as nitrofurantoin, non-steroidal anti-inflammatory drugs, opiates, anti-convulsants like carbamazepine and dilantin, anti-arrhythmic drugs, hydralazine, penicillamine and gold salts). Amiodarone lung toxicity is relatively frequent and is considered as a prototype of drug-induced ILD.

Radiation administered for thoracic malignancies, especially when used in a higher dose, is another iatrogenic cause of ILD. Radiation can induce both pulmonary and mediastinal fibrosis. Inhalation of toxic gases and fumes, such as methyl isocyanate and nitrogen dioxide can cause interstitial involvement. In view of a shorter exposure, it is generally self-limiting but chronic

pulmonary involvement from inhalational exposure is also possible.

Hypersensitivity pneumonias (extrinsic allergic alveolitis) of acute, sub-acute or chronic onset which occur on exposure to known environmental or occupational antigens include farmer's lung, byssinosis, air-conditioner's lung, bird-fancier's disease and mushroom picker's disease. They may also occur in individuals working with different chemicals, drugs, pharmaceutical agents and laboratory animals. This is especially so in the industrial workers engaged in the manufacturing/processing of rubber foam, azo-dyes, tetracyclines, ampicillin, antihypertensive drugs and others.

EPIDEMIOLOGY

Interstitial lung disease in India was considered to be rare in the past. An increased awareness, wider availability of high-resolution computed tomography (HRCT) and other diagnostic tests have led to an increased recognition of the problem. ILDs constitute about 10% to 15% of the patients with respiratory diseases, seen at any large hospital in the country. About 50% of the ILDs are idiopathic in origin while others are associated with identifiable diseases, most commonly, a CTD. UIP, also known as IPF is the most common form of IIP.

PATHOLOGY AND PATHOGENESIS

The normal pulmonary interstitium comprises of the anatomical space between the alveolar and the capillary basement membranes. It contains mesenchymal and connective tissue cells, and extra-cellular matrix composed of collagen, elastin and proteoglycans. The interstitial involvement progressively encroaches the alveolar spaces, the terminal bronchioles and also the overlying pleura. It results in a diffuse involvement of the lung parenchyma.

Characteristically, there is cellular infiltration and thickening of pulmonary interstitium and of alveolar walls, as well as the presence of mononuclear cells in the alveolar lumen. The cellular exudate comprises primarily of alveolar macrophages but lymphocytes, neutrophils, eosinophils and plasma cells are also present. Although the total collagen component of lungs remains normal, the ratio of type I to type III collagen is increased. The advanced-stage disease is characterised by extensive fibrosis, obliteration of the lumen of alveoli and formation of multiple cysts, also called as the honeycomb lung.

There is no clear understanding of disease pathogenesis. Chronic inflammation, recurrent epithelial injury and impaired damage repair are some of the possible reasons of pulmonary fibrosis. Several new mechanisms of pulmonary fibrosis have evolved in the last decade. Pulmonary fibrosis is considered to result from an aberrant defence reaction with failure of mechanisms which are normally responsible for repair. It is now recognised that there is persistence and/or repetitive injury responsible for inflammation followed by recruitment of a host of inflammatory cells. The different cytokines and other mediators released by the activated cells, especially macrophages, are able to stimulate fibrosis. Local oxidative lung damage may also result from the reactive oxygen species and proteases released by the inflammatory cells, such as neutrophils and eosinophils. There is increased procoagulant activity, apoptosis, angiogenesis, and fibrogenesis. A genetic predisposition is also likely.

CLINICAL FEATURES

The prototype idiopathic ILD commonly involves the older adults of both sexes in the 6th or 7th decade of life. But ILDs secondary to a connective tissue disorder such as PSS, RA or SLE are more common in the young female patients. Onset is generally sub-acute, although acute forms are also known. In particular, AIP which is frequently fatal, presents with a rapid onset of acute respiratory distress. It rapidly results in diffuse alveolar damage.

Most often, the patients present with progressive breathlessness and dry, unproductive cough which is occasionally accompanied by scanty mucoid expectoration. Constitutional symptoms of malaise, weakness, fatigue, myalgias, fever, arthralgia and weight loss are frequently seen in association with a CTD.

Finger-clubbing is present in about one-third of the patients. Hypertrophic osteoarthropathy is rarely seen. Cyanosis is generally absent at rest but desaturation occurs and cyanosis appears even after mild exercise. Cyanosis may be present even at rest in an advanced state of disease. Physical examination of the chest may reveal tachypnoea, reduced chest expansion and intercostal retractions. Breath sounds are vesicular and quite distinct. Broncho-vesicular or bronchial breathing is heard in the presence of a consolidation, a cavity or an advanced disease. The bibasal dry, end-inspiratory 'velcro' crackles are quite characteristically heard in most patients of IPF. These crackles are attributed to the snap opening up of collapsed alveoli when equalisation of pressure occurs between the alveolar spaces and the proximal bronchiole during inspiration.

Patients with secondary ILDs may also show symptoms and signs of the underlying diseases. Patients with CREST syndrome (calcinosis, Raynaud's phenomenon, oesophageal dysfunction, sclerodactyly and telangiectasia) may present with pulmonary hypertension as a primary manifestation. Pulmonary hypertension and chronic cor pulmonale, chronic congestive failure develop in a long standing disease. Acute exacerbation or an 'accelerated stage' indicates a rapid deterioration without the presence of an identifiable cause.

DIAGNOSIS

Diagnosis of ILD is generally suspected on history and clinical examination. But differential diagnosis from other causes of similar clinical presentation may be needed in some cases. Cardiac failure and pulmonary thromboembolism (PE) are the two important diseases requiring careful exclusion. Cardiac failure is diagnosed on the basis of history, clinical findings, electrocardiogram (ECG), chest radiography and echocardiography. Chronic and silent pulmonary thromboembolism may sometimes pose difficulties when more specific investigations such as the ventilation perfusion scans, contrast enhanced computed tomography and pulmonary angiography are helpful. Algorithm I shows approach to diagnosis (**Figure 1**).

Establishing the Cause of ILD

Following investigations offer a variable help in establishing the cause of ILD.

Chest radiography

The interstitial infiltrates are seen as discrete, linear, nodular or reticulonodular shadows diffusely distributed in both the lungs (**Figure 2**). The individual nodular shadows are usually of less

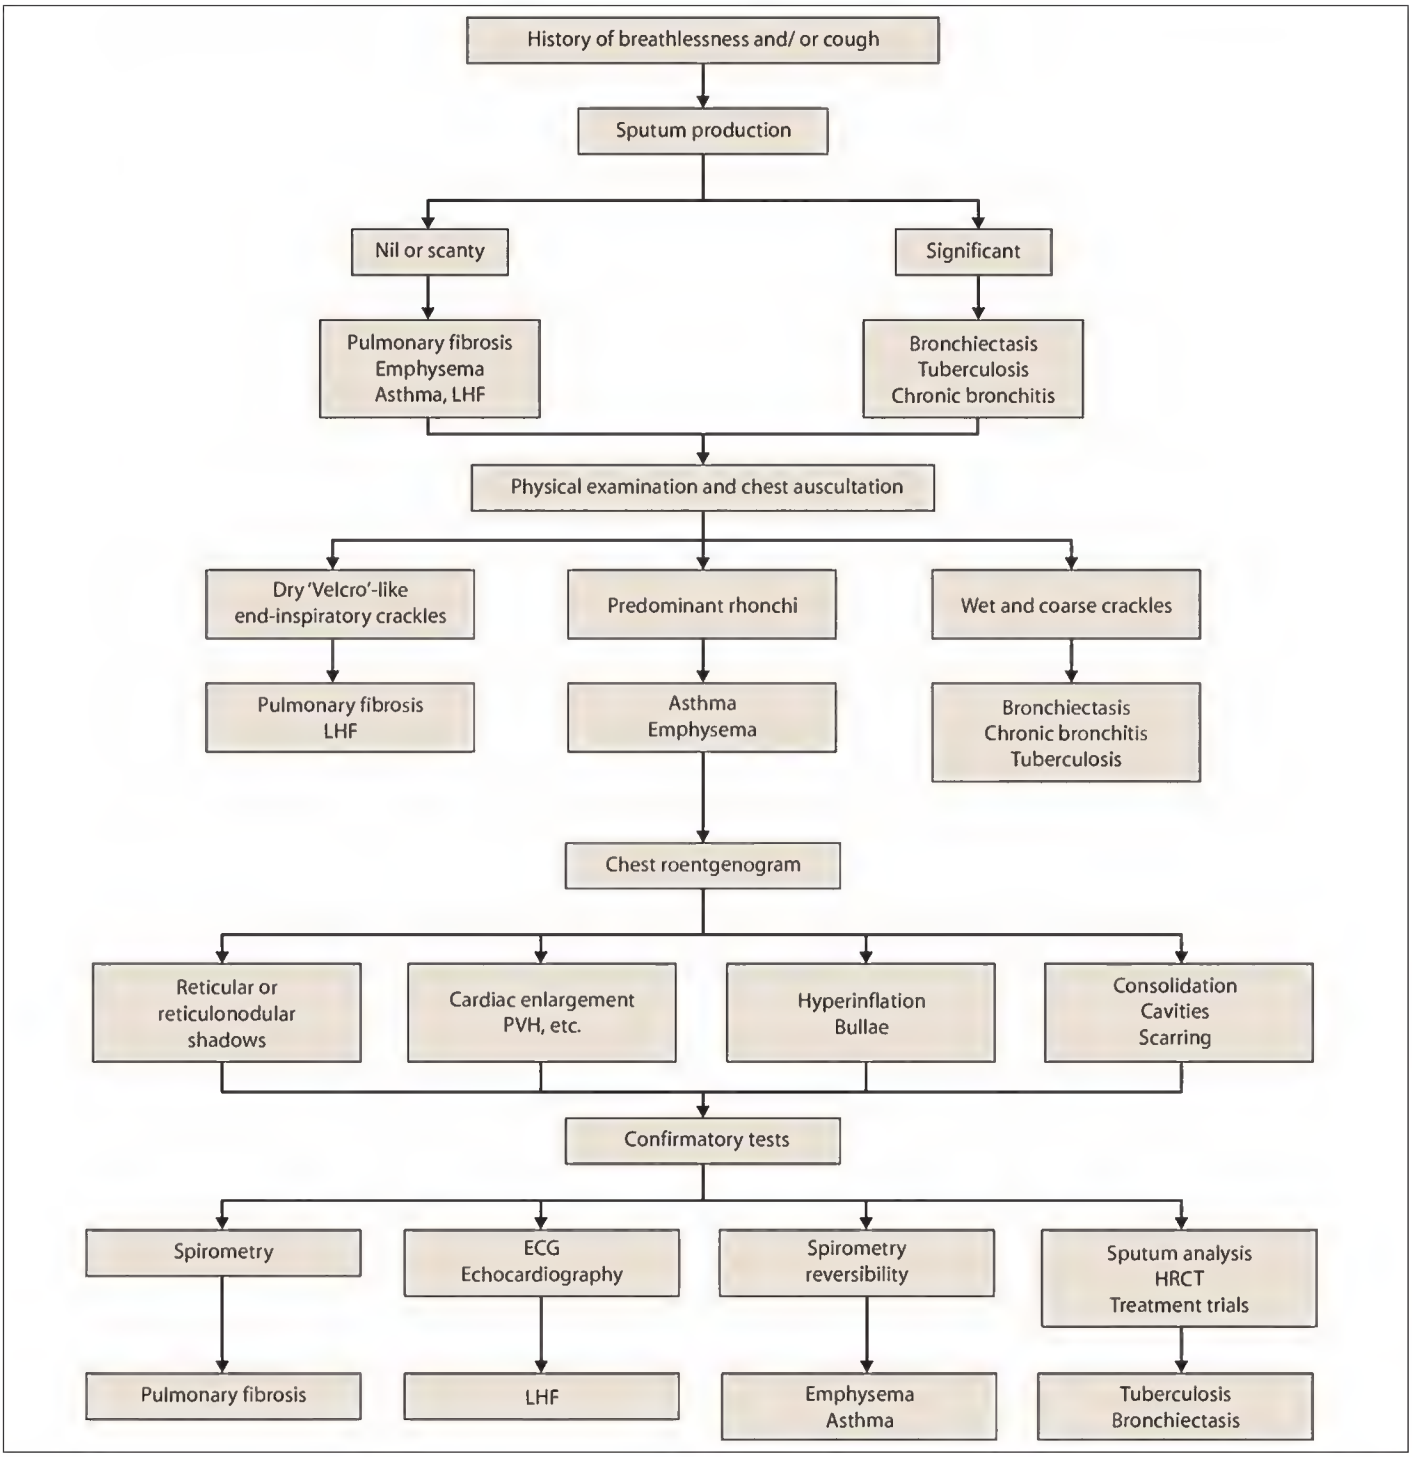

Figure 1: Algorithm for diagnosis of pulmonary fibrosis in a patient with respiratory symptoms.

HRCT = High resolution CT scan; LHF = Left heart failure; PVH = Pulmonary venous hypertension.

than 2 mm in diameter. They may also coalesce and form larger nodules. The shadows are generally bibasilar in distribution in early stages. In later stages, diffuse involvement occurs all over the lungs. Upper lobe involvement suggests diseases, such as pneumoconioses, sarcoidosis and hypersensitivity pneumonias.

Presence of diffuse mottling or ground-glass appearances may suggest an active stage of diffuse alveolitis. Miliary distribution throughout the lung fields is characteristically seen in tuberculosis (TB), pneumoconiosis, and sometimes in sarcoidosis. Occasionally, fluffy alveolar shadows may be present due to the coalescence of interstitial shadows or a complicating infection. A normal chest radiograph does not exclude ILD. In advanced disease, when fibrosis is extensive, the lungs get shrunken and reduced in volume. Small, uniform-sized, quadrangular cystic spaces, representing patent bronchioles, give the typical appearances of a honeycomb lung.

The HRCT offers a much better view of lung parenchymal involvement. The classical picture of bibasilar reticular and/or nodular infiltrates, honeycombing and absence of lymphadenopathy support the diagnosis of IPF (**Figures 3A to C**). Pathology is considered uncertain if radiographic findings are atypical, lung involvement is mild or patchy and/or there is presence of hilar/mediastinal lymphadenopathy. The HRCT is of great use in classifying IPF. The HRCT features of subpleural septal

Figure 2: Chest radiograph showing diffusely distributed infiltrate.

thickening, traction bronchiectasis, and ground-glass attenuation can be considered as definite UIP and lung biopsy can be avoided (**Figures 3A to C**). Diseases, such as sarcoidosis, histiocytosis and lymphangitis have more characteristic patterns. The HRCT is also of some help in making a quantitative assessment of pulmonary fibrosis. Spiral CT gives even a better resolution, especially in a patient with tachypnoea who cannot hold his breath.

Pulmonary function tests

Most ILD demonstrate a restrictive defect on spirometry. Tidal volumes are generally small and both the vital capacity and the total lung capacity are reduced. Expiratory flows are normal or even 'supranormal'. Airway obstruction, characterised by reduced forced vital capacity (FVC) and forced expiratory flows, can occur in patients with hypersensitivity pneumonias, and in smokers. Reduced diffusing capacity (DLCO) and arterial hypoxaemia (reduced PaO_2) may not be present in the early stages. Some degree of arterial hypoxaemia on exercise is almost always demonstrable (all these are given in a algorithm).

Bronchoalveolar lavage (BAL)

Assessment of cellular response in the BAL fluid, although is not conclusive, may help in the differential diagnosis. There is lymphocytic predominance in sarcoidosis and TB, neutrophilic in pulmonary fibrosis. Presence of eosinophils may suggest hypersensitivity reactions or pulmonary eosinophilia. Infective micro-organisms such as the mycobacteria, fungi, or *Pneumocystis jirovecii* can be isolated from BAL fluid. Presence of lymphocytosis in the BAL fluid is shown to predict a better response to corticosteroid therapy. An increase in the alkaline phosphatase/albumin ratio in BAL fluid on a repeated study reflects progression of fibrosis.

Other investigations

Although non-specific, haematological investigations provide useful information. A high erythrocyte sedimentation rate (ESR) of more than 50 mm in first hour occurs in CTD, malignancies, infections, and systemic vasculitides. Unexplained anaemia is seen in diffuse alveolar haemorrhage and CTD. Mild to moderate leukocytosis is common in both primary and secondary ILD.

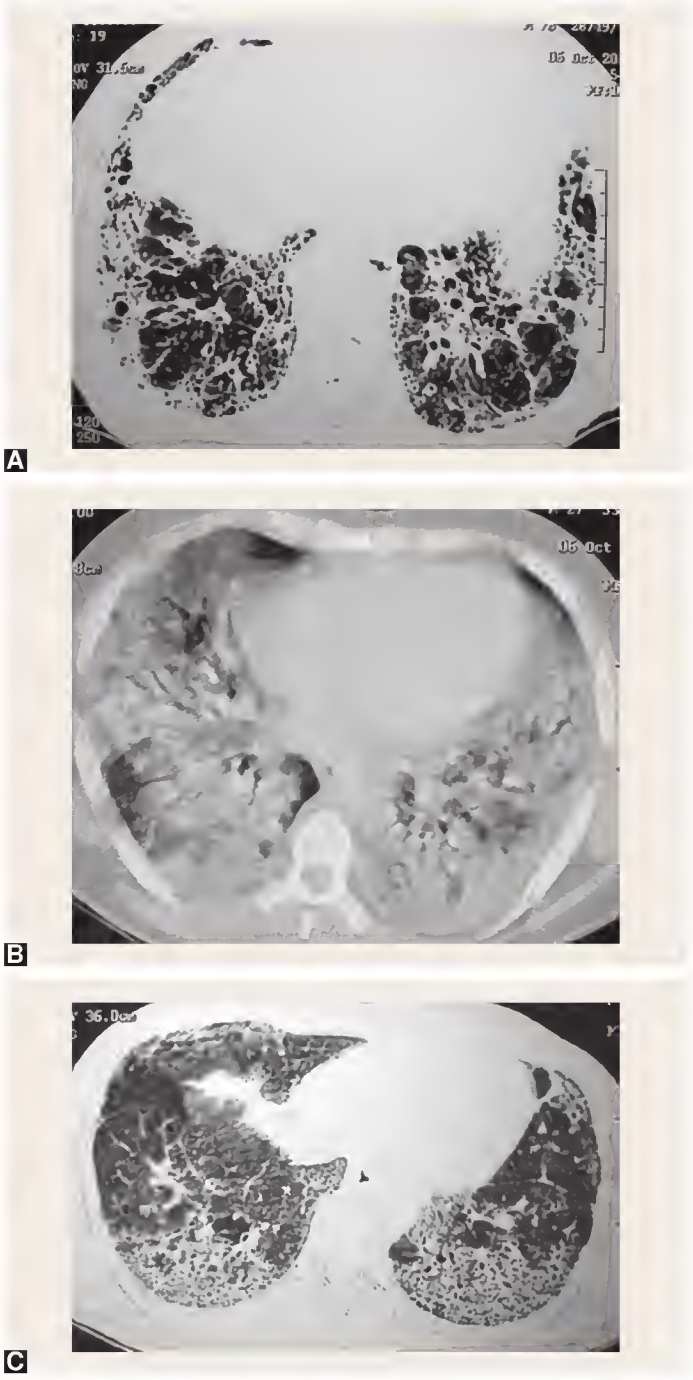

Figure 3A to C: (A) HRCT chest-showing IPF, (B) UIP, (C) and bronchiectasis, suggestive of ILD.

Eosinophilia is more characteristically seen in eosinophilic and hypersensitivity pneumonias, vasculitides, sarcoidosis, and drug-induced lung diseases. Occasionally, there is leucopenia and/or thrombocytopaenia.

Abnormal liver or renal function tests suggest the involvement of these organs. Elevated calcium may be seen in sarcoidosis and malignancies. Increased enzymes, such as creatinine phosphokinase and aldolase, are present in polymyositis and dermatomyositis. Increased serum angiotensin converting enzyme (SACE) in sarcoidosis is quite characteristic but may be seen in silicosis, hypersensitivity pneumonias, and other diseases.

A number of immunological parameters are described in CTDs and other ILDs. Hypergammaglobulinaemia, positive serum

auto antibodies (e.g. the anti-nuclear factor) and circulating immune complexes may be seen. Anti-basement membrane antibodies in Goodpasture's syndrome, anti-neutrophil cytoplasmic antibody (C-ANCA) in Wegener's granulomatosis, Churg-Strauss syndrome and Systemic necrotising vasculitis, and anti-Jo_1 antibody in polymyositis-dermatomyositis are generally considered characteristic.

Radionuclide scanning using Gallium–67, and positron emission tomography (PET) with glucose FDG isotope have a place to identify disease-activity and to predict response to therapy. Similarly, the clearance of aerosolised technetium-99m diethylenetriaminepenta-acetic acid (DTPA) is markedly increased in patients with inflammatory lung diseases including sarcoidosis.

Lung biopsy

Diagnosis of IIPs is fairly specific on clinical features and radiographic characteristics seen on HRCT. Lung biopsy is required only when the findings are atypical, to exclude an infective vasculitides or some other undiagnosed cause of ILD is suspected. It may also help to predict the response to treatment and prognosis of a patient. Patients with usual interstitial pneumonia do worse than those with other histological subsets of IIPs. Transbronchial lung biopsy (TBLB) with the help of fiber-optic bronchoscopy (FOB) is less rewarding, especially in patients with IPF. In sarcoidosis, the positivity rates of TBLB may be as high as 70% to 80%. Many patients of IPF cannot be subjected to TBLB in view of an inadequate biopsy size and risks involved with FOB. Transthoracic or open surgical approach provides a better option to obtain lung tissue. These are summarised in algorithm.

MANAGEMENT

The management of ILD should follow an algorithmic approach (**Figure 4**). In the absence of a satisfactory, definitive treatment of IPF, most objectives (**Table 2**) are achieved with supportive and symptomatic therapy. Several different groups of drugs are employed in its treatment (**Table 3**). Supportive treatment is provided for respiratory failure, pulmonary hypertension, cor pulmonale and congestive cardiac failure, wherever indicated. Long-term pulmonary vasodilators are not shown to prevent the development of pulmonary hypertension. An acute increase in symptoms and presence of fever with or without mucopurulent expectoration raises the suspicion of a respiratory infection necessitating treatment with antibiotics. To assess the response to therapy and to monitor its progress, a clinical, radiological and physiological (CRP) score has been used in the past. It is difficult to frequently repeat invasive investigations, such as the BAL or lung biopsy. It is generally adequate to rely on clinical picture, simple spirometry, and a plain chest radiograph.

Table 2: Objectives of Treatment of ILD

Provide symptom relief
Slow down disease progression
Prevent complications
Improve quality of life
Prolong survival
Prevent treatment complications
End-of-life care – Palliation treatment

Anti-Inflammatory Therapy

Anti-inflammatory therapy has remained the mainstay of treatment. Minimal to significant improvement is reported with the use of anti-inflammatory agents. But their efficacy remains unproven and the toxicities are substantial. The commonly used criteria to start anti-inflammatory therapy include the presence of severe or worsening clinical symptoms, younger age of the patient and shorter duration of illness.

Table 3: Drugs Employed for the Treatment of ILD

Treatment of Primary Disease responsible for a secondary ILD
Treatment of primary ILD
Anti-inflammatory drugs
Corticosteroids*
Azathioprine*
Cyclophosphamide
Anti-fibrotic agents
Colchicine
Pirfenidone*
Pentoxyphylline
D-Penicillamine
TGF-beta antagonist
Interferon-gamma
Anti-oxidant agents
N-acetylcysteine*
Nitric oxide synthase inhibition
Supportive and symptomatic treatments*
Oxygen
Pulmonary vasodilators
Diuretics
Antibiotics (if infection)

*Note: (i) Drugs marked * are generally used in clinical practice; (ii) Trial treatment is given for 3 to 6 months. Taper treatment in case of nil response; (iii) Avoid corticosteroids in the presence of complicating co-morbidities.*

Corticosteroids are the most frequently used anti-inflammatory agents. Their role to provide long-term relief and to prolong survival is doubtful. Prednisolone is administered in a dose of 1 to 1.5 mg/kg for a period of about 6 to 12 weeks. Maintenance daily dose of about 15 to 20 mg is continued for 1 to 2 years or more.

Other immunosuppressive agents, such as azathioprine or cyclophosphamide, administered along with prednisolone are shown to do better. Intravenous cyclophosphamide used as intermittent pulse therapy (1 gm to 1.3 gm per month) is shown to provide some relief. A combination of low-dose corticosteroids and azathioprine is frequently employed for maintenance treatment continued for 2 to 3 years after the disease onset. The role of anti-inflammatory therapy is limited to patients with predominant inflammation. The risks, especially the use of prolonged corticosteroids and other immunosuppressants, often outweigh the benefits of therapy.

Anti-Fibrotic Agents

There is a greater trend to rely on anti-fibrotic drugs for the treatment of ILDs. Of the several anti-fibrotic agents which had been tried, colchicine was considered the safest alternative. It was recommended in a dose of 0.6 to 1.2 mg per day for a period of at least 6 to 12 months. D-penicillamine and pirfenidone are other drugs which have been tried with variable results. Interferon gamma B, TGF-beta and several other agents, initially shown to have promising results, are also equally ineffective in their clinical use.

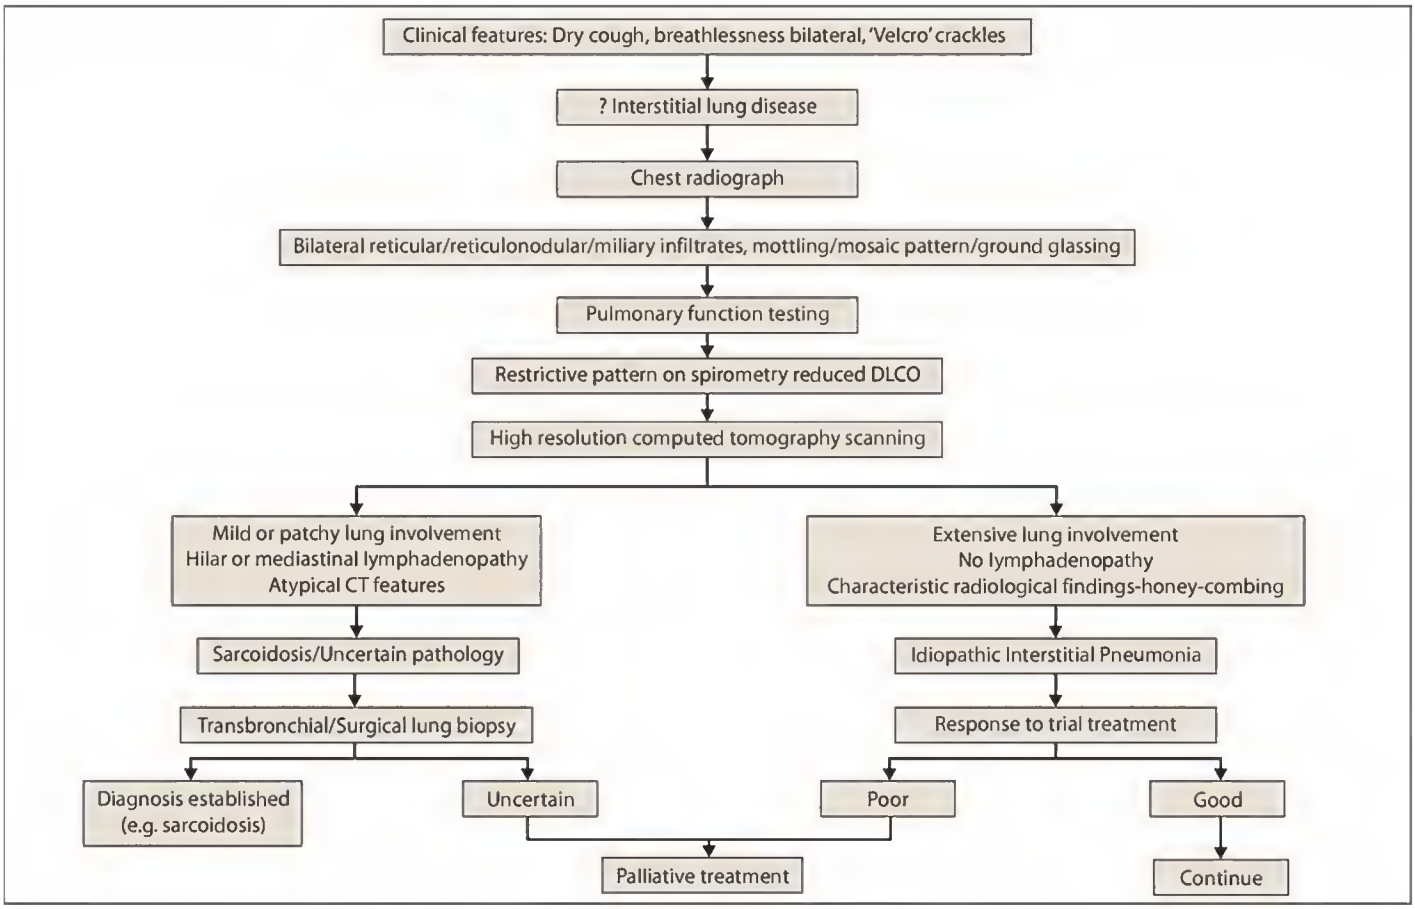

Figure 4: Management algorithm for ILD.

Other Treatments

Anti-oxidants, such as N-acetylcysteine to reduce oxidative stress, are shown to offer some clinical advantage when used along with anti-fibrotic agents. Drugs targeted to prevent or reduce apoptosis, angiogenesis and coagulant activity may find some use in the future. Presently, no drug from these groups is available for clinical use.

It is a better option to resort to symptomatic palliative therapy and withdraw immunosuppressive drugs in case there is no response in the initial 3 to 6 months of use and for end-stage disease.

Lung transplantation is the only hope for the advanced, end-stage disease. Single lung transplantation is recommended in most patients. Five years survival is reported in up to 40% to 60% of the patients. The common post-transplant complications includes the risk of rejection, multiple opportunistic infections in an immunosuppressed host, and organising pneumonias. The lack of availability of organ for transplantation and very high cost involved in the procedure are the limiting factors.

PROGNOSIS

Prognosis of ILDs, secondary to systemic diseases or other causes is determined by the natural course of the underlying disease. Prognosis of primary IIPs is variable. While NSIP, DIP and RBILD respond better, the IPF is progressive and fatal. The survival has not significantly improved in the last 50 years or so from that reported in the 1960s. The median survival of IPF is about 4 years. Acute interstitial pneumonia and acute exacerbation of IPF are rapidly fatal, sometimes in a course of a few weeks or months.

23.12 Eosinophilic Lung Disease and Tropical Pulmonary Eosinophilia

Farokh E Udwadia

INTRODUCTION

Pulmonary eosinophilia is characterised by pulmonary infiltration with a predominant eosinophilic exudate, almost always accompanied by a significant rise in the peripheral eosinophilic count. In clinical practice, the term pulmonary eosinophilia is often used to denote peripheral eosinophilia with pulmonary shadowing on the chest radiograph without an exact tissue diagnosis always being made. This may be incorrect, as peripheral eosinophilia and the pulmonary infiltrate (which may be non-eosinophilic) in a given patient may have separate aetiological causes. The association of pulmonary shadowing with peripheral eosinophilia has been described by the use of various semantic terms such as Loeffler's syndrome (transient pulmonary infiltrates, lasting for <3 weeks with peripheral eosinophilia), the pulmonary infiltration with eosinophilia (PIE) syndrome, eosinophilic pneumonia and eosinophilia among others. Pulmonary eosinophilia as observed in the tropics is best classified as follows (**Table 1**).

Table 1: Causes of Pulmonary Eosinophilia

Pulmonary eosinophilia due to human filarial infections
Pulmonary eosinophilia due to other parasitic infections
Allergic bronchopulmonary aspergillosis
Hypersensitivity response
Drugs
Pollen
Other fungi
Other antigens
Asthmatic pulmonary eosinophilia
Churg-Strauss syndrome
Cryptogenic eosinophilic pneumonia
Hypereosinophilic syndrome

PULMONARY EOSINOPHILIA DUE TO PARASITIC CAUSES

Filarial Infection

Human filarial infection generally results in endemic filariasis. However, an unusual clinical variant of filarial infection is the most common cause of pulmonary eosinophilia in the tropics. This variant results from a hypersensitivity response, chiefly within the lungs to human microfilariae and is termed tropical eosinophilia.

Other Parasitic Infections

Other parasitic infections that can give rise to pulmonary eosinophilia include infections caused by Ascaris and other nematodes, *Toxocara canis*, *Toxocara cati*, ankylostoma and strongyloidiasis.

PULMONARY EOSINOPHILIA DUE TO NON-PARASITIC CAUSES

Allergic bronchopulmonary aspergillosis (ABPA) is the most frequent and important among the non-parasitic causes. Other causes include hypersensitivity response to drugs, other fungi, pollen and a host of other antigens; asthmatic pulmonary eosinophilia, when not due to ABPA, the Churg-Strauss syndrome, cryptogenic eosinophilic pneumonia, which is usually chronic and occasionally acute (may not always be accompanied by peripheral eosinophilia); and the hypereosinophilic syndrome.

TROPICAL EOSINOPHILIA

Historical Background

In 1943, Weingarten used the term tropical eosinophilia (TE) when describing a syndrome characterised by severe spasmodic bronchitis, eosinophilic leucocytosis, and disseminated mottling of both lungs. He also described the successful treatment of tropical eosinophilia following the use of neoarsphenamine (an arsenical preparation). Further work over many subsequent years has now elucidated the histopathology, the natural history, immunology, and aetiology of this exotic syndrome.

Epidemiology

The syndrome is particularly endemic in India, Sri Lanka, South-East Asia and Africa, and has been reported from filarial epidemic areas worldwide. In India, its endemicity is mostly marked along the Western Coastal Strip around Bombay, Goa, Kerala, the Eastern Coast and in Bengal, Bihar, and Orissa which are also endemic to filarial infection.

Aetiology

Presently, TE is considered to be a variant of human filarial infection resulting from hypersensitivity to microfilariae liberated by *Wuchereria bancrofti and Brugia malayi*. This concept is based on serological, histopathological, therapeutic, and immunological evidence.

Clinical Features

Tropical eosinophilia can involve many organ systems e.g. liver, spleen, lymph glands but chiefly involves the lungs. The pulmonary manifestations include paroxysmal cough, breathlessness, wheeze, scattered auscultatory crackles, pulmonary infiltrates, and an absolute eosinophilic count greater than 3000 to 3500/mm^3. These symptoms are most marked in the night but are often also present in the day. Non-specific systemic features include fever, malaise, and weight loss. The absolute eosinophil count in hyperacute cases can be as high as 50,000/mm^3. The non-pulmonary manifestations of TE include hepatosplenomegaly, lymphadenopathy, muscle pains and muscle weakness, and occasionally, diarrhoea with weight loss.

Radiology

The radiological features vary. Prominent hila with heavy vascular marking at the bases are often observed. Fluffy reticulonodular shadows over the mid zones and bases of the lungs may also be seen. At times, the picture is of miliary mottling indistinguishable from miliary tuberculosis. In 20% of the patients, the chest

radiograph is normal even though the lung histopathology is typical of TE. In the early part of its natural history, TE invariably responds to diethylcarbamazine. Patients who remain untreated, who have a long history or who respond inadequately to diethylcarbamazine, may progress to chronic increasing respiratory disability due to moderately severe pulmonary fibrosis.

Lung Function

Two patterns are observed. A predominant restrictive pattern with low forced vital capacity (FVC), total lung capacity (TLC), residual volume (RV) and a lowered diffusion capacity due to reduced area of membrane available for diffusion. A combination of airways obstruction and restriction where the forced expiratory volume in the first second (FEV1) to FVC ratio being reduced in addition to the restrictive pattern described above.

These findings improve and return to normal after three to four months in patients who respond well to diethylcarbamazine. In patients who frequently relapse and in patients with a long standing history, there is a progressive increase in the restrictive pattern due to moderate pulmonary fibrosis. The degree of pulmonary function impairment in these patients is, however, never as marked as in severe cryptogenic fibrosing alveolitis. Pulmonary hypertension and cor pulmonale in uncomplicated TE do not generally occur.

Histopathology and Natural History

In the early part of its natural history, TE is histopathologically characterised by a dense eosinophilic pneumonia and bronchopneumonia; later (6 months to 2 years after the onset of symptoms), a mixed cell exudate of eosinophils, lymphocytes and mononuclear cells is observed, together with some degree of fibrosis. Breathlessness on exertion is now the predominant symptom. Even later (symptoms >2 years), the eosinophils in the lungs are scanty; the exudate is lymphocytic with mononuclear cells and there may be well marked fibrosis. Increasing respiratory disability is observed in chronic cases. In some long standing cases, the peripheral eosinophilia wanes and the presenting feature is increasing breathlessness on exertion with respiratory disability. If observed for the first time at this late stage, the relation of the clinical feature to TE may not be recognised. Such a patient may then be dubbed as bronchitic or as suffering from idiopathic pulmonary fibrosis. It is noteworthy that histopathological studies have demonstrated the presence of disintegrating fragments of microfilariae in the lung, as also in the liver and lymph nodes when these are involved.

Immunology

In TE, microfilariae from a mature gravid human filarial parasite are periodically released but are promptly trapped within the lungs and thus removed from the circulation. Microfilaraemia in the blood is thus very rarely observed. Within the lungs, microfilariae elicit a strong type I, type III, type IV immunological response. High levels of filarial specific immunoglobulin (Ig)E, IgG, and IgM are found in the lower respiratory epithelial lung fluid. The role of the eosinophil is crucial in this response. The eosinophil serves a dual purpose. It helps to destroy the microfilarial parasite and yet also has a destructive effect on lung tissue due to the release of eosinophil granule components. The latter includes eosinophilic major protein, peroxidases and collagenases, all known to injure lung parenchymal cells.

If microfilariae succeed in running the gauntlet of the pulmonary circulation, they reach the systemic circulation and cause an eosinophilic reaction in the reticuloendothelial system (liver, spleen, lymph glands and rarely, the muscles and the gastrointestinal tract). Thus, though TE chiefly involves the lung, other systems may be involved. The reason for the difference in the immunological response to the same filarial parasite in patients with endemic filariasis and in those with TE remains unknown. Racial and genetic factors are important. Age at which infection occurs and the frequency of exposure may also determine difference in immunological response.

Treatment

Diethylcarbamazine is specific for treatment in a dosage of 5 mg/kg/day administrated preferably for a period of three weeks. About 4% to 5% of the patients even in the earlier part of their natural history respond inadequately and 20% to 40% of patients with a longer duration of symptoms (2 to 5 years) fail to respond. The lack of response to patients with a long standing history is explicable because the drug cannot be expected to act on increasing fibrosis within the lung. It has been suggested that repeated monthly courses of diethylcarbamazine at 2 to 3 monthly intervals for a period of 1 to 2 years may reduce the morbidity of patients with TE who live in endemic zones and who are subject to relapses and repeated infections. The role of corticosteroids in patients with increasing fibrosis is underdetermined but may well merit a try.

PULMONARY EOSINOPHILIA AND OTHER PARASITIC INFECTIONS

Other nematodes (notably ascarial infection), which at some stage in their life cycle go through the lungs can excite an immunological response with clinical features indistinguishable from tropical eosinophilia. In addition, ascarial infection would also respond to diethylcarbamazine. There are a number of physicians who, therefore, consider tropical eosinophilia to be a syndrome having many aetiologies. However to prevent the term TE from becoming a 'catch all' waste paper basket for all patients in the tropics with cough, breathlessness and peripheral eosinophilia, it would be best to define the above symptom complex in relation to aetiology. This can only be possible if cheap easily available tests for human parasitic infections are locally available. Till then, to avoid semantic confusion, it is suggested that the use of the term TE should be confined to a symptom complex which is caused by an unusual hypersensitivity response to the human filarial parasite, responding at least in the early part of its natural history to diethylcarbamazine.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic bronchopulmonary aspergillosis generally, though not always, occurs against the background of asthma and is due to a hypersensitivity response to inhaled spores of *Aspergillus fumigatus*. These spores thrive within bronchial secretions, from hyphae, liberate antigen thereby exciting an immune response leading to an eosinophilic exudate within bronchial walls and adjacent alveoli. Type I, III and IV reactions are involved and there is an accumulation of antigen- specific antibodies, IgE, IgG, and IgA within the involved lung tissue.

Clinical Features

Clinical features include fever, an exacerbation of asthmatic symptoms, and peripheral eosinophilia (>5x10^9/L). The chest radiograph shows presence of 'shadows' (often migratory) chiefly involving the upper lobes of one or both lungs. Coughing

is often associated with expectoration of viscid brownish pellets of mucus containing the fungus. Bronchial casts may occasionally be coughed up.

Investigations

Sputum or bronchoalveolar lavage (BAL) fluid examination reveals hyphae of *Aspergillus fumigatus* on staining and culture. The chest radiograph shows fleeting pulmonary shadows. Segmental or lobar atelectasis may occur. The skin patch test to *Aspergillus fumigatus* antigen is positive. Serum precipitins (IgG) against *Aspergillus fumigatus* are positive. The total IgE and antigen-specific IgG are raised in the serum.

Repeated episodes of bronchopulmonary aspergillosis lead to destruction of bronchial walls and surrounding alveoli resulting in proximal bronchiectasis and bilateral upper lobe fibrosis. Permanent radiologic abnormalities may include ring shadows due to dilated bronchi, 'gloved-finger' shadows due to secretions in dilated bronchi, 'tram line' shadows due to thickened bronchial walls extending outwards from the hilum. Pulmonary shadows due to ABPA in asthmatic patients are often wrongly diagnosed and treated as tuberculosis.

Treatment

Prednisolone in a dosage of 30 mg/day for five days and then tapered off within 15 days resolves the shadows and relieves symptoms. Attacks may recur necessitating frequent courses of corticosteroids. A small maintenance dose of 5 to 10 mg/day may give better control of asthma and prevent frequent episodes of ABPA. Overall, good control of asthma by conventional therapy is important.

PULMONARY EOSINOPHILIA DUE TO DRUGS, POLLEN AND OTHER ANTIGENS

Pulmonary eosinophilia due to drugs, pollen and other antigens may take the form of peripheral eosinophilia with transient pulmonary shadows and infiltrates (Loeffler's syndrome) or as with hypersensitivity to drugs may lead to fairly extensive eosinophilic infiltrates, with pulmonary shadows that are either diffuse or distributed peripherally. The clinical picture is that of fever, cough and breathlessness coupled with pulmonary shadows. These resolve within weeks of stopping the offending drug. Common drugs causing pulmonary eosinophilia are listed in **Table 2**.

Table 2: Common Drugs Causing Pulmonary Eosinophilia

Antibiotics (e.g. penicillin, minocycline)
Sulpha drugs
Trimethoprim-sulphamethoxazole
Nonsteroidal anti-inflammatory agents
Carbamazepine
Tricyclic antidepressants
Nitrofurantoin
Penicillamine

ASTHMATIC PULMONARY EOSINOPHILIA

Pulmonary eosinophilia may rarely occur in patients with bronchial asthma in whom all tests for ABPA are negative. In patients with intrinsic asthma, this rare form of pulmonary eosinophilia may well be the prevasculitic form of Churg-Strauss syndrome. In atopic patients with extrinsic asthma, eosinophilic pulmonary infiltrates may be due to a reaction to an unidentified allergen. Asthmatic pulmonary eosinophilia responds well to corticosteroids.

Churg-Strauss Syndrome

In Churg-Strauss syndrome a pulmonary vasculitis is associated with pulmonary eosinophilia. The syndrome evolves in three phases. An initial phase of asthma is often present for many years. The second phase is characterised by tissue and peripheral eosinophilia. The lungs are most commonly involved in this phase. The chest radiograph at this stage shows one or more 'shadows' in one or both lungs. These shadows may be flitting in character and when present against the background of long standing bronchial asthma with peripheral eosinophilia suggest the correct diagnosis. The final is the life threatening stage of systemic vasculitis; the lungs, gastrointestinal tract, peripheral nerves and skin being most frequently involved. Mononeuritis multiplex is a frequent presentation. Skin lesions take the form of purpuric lesions, nodules or vasculitic ulcers. Cardiac involvement causes abdominal pain, haematemesis or melana. A chest radiograph in the third phase of the disease most often shows non-cavitating bilateral nodular or confluent shadows. Pleural effusions may be occasionally seen.

The perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA) test is often positive. A lung biopsy may be necessary to distinguish the Churg-Strauss syndrome from other forms of pulmonary eosinophilia. Prednisolone in a dose of 1 mg/kg controls the disease. A maintenance dose may be necessary for an indefinite period of time.

CRYPTOGENIC EOSINOPHILIC PNEUMONIA

Cryptogenic eosinophilic pneumonia is characterised by dense pulmonary infiltrates and peripheral eosinophilia with or without a background of asthma. Occasionally, peripheral eosinophilia is absent. The disease is common in females above 35 years of age. The clinical features of breathlessness, cough, fever are associated with pulmonary shadows which are more peripherally distributed (exactly the opposite of the bilateral centrally placed shadows observed in pulmonary oedema). The disease is generally chronic but may rarely be acute in onset. It responds well to corticosteroid therapy (prednisolone in a dose of 1 mg/kg). Recurrence is not uncommon after stoppage of steroid therapy.

HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome is a systemic disorder of unknown aetiology which generally occurs in males and is characterised by a very high peripheral eosinophilia (>20x10^9/L), fever, weight loss with dense eosinophilic infiltration of the heart, lung, skin, central nervous system, liver, spleen, and other organs. Treatment with oral prednisolone is often effective. The use of vincristine and hydroxyurea may improve prognosis.

23.13 Occupational and Environmental Lung Diseases

Ashutosh Nath Aggarwal

DEFINITION AND PATHOGENESIS

Pneumoconiosis is a generic term for the lodgement, and subsequent non-specific pulmonary reaction, of any inhaled mineral or organic dust in the lungs irrespective of the effects (excluding malignancy and asthma). These respiratory disorders are a heterogeneous group. They are commonly categorised based on the time of the development of obvious disease (acute or chronic/prolonged exposure) and on the specific agent responsible for the disease. Three broad factors: (a) intensity and duration of exposure; (b) individual susceptibility; and (c) the nature, chemistry and geometric, aerodynamic and surface properties of each specific agent – influence the character and severity of pulmonary reaction to mineral dusts. The particles leading to pneumoconiosis need to be small enough (generally 0.5 to 5 μm) to reach the respiratory bronchioles and get deposited there.

MAGNITUDE OF THE PROBLEM

Over the last few decades, the occurrence and severity of the usual occupational lung disorders have progressively decreased in industrially developed countries. This has largely been brought about by: (a) improvements in work environment; and (b) enforcement of work-related safety legislation. However, working conditions remain far from satisfactory, let alone healthy, in less developed nations, including India. The problem in India is further compounded by: (a) the lack of availability of exact figures relating to prevalence and incidence of occupation-related diseases; (b) inadequate facilities for screening, diagnosis and management of these disorders; and (c) absence of proper mechanisms for notification and worker compensation.

RECOGNITION AND PATIENT EVALUATION

Four important criteria are useful to guide the diagnosis of an occupational lung disease. First, the patient should have been exposed to a known hazardous agent at workplace. Second, the latency between exposure, and onset of clinical manifestations, should be appropriate for the agent suspected to result in lung disease. This duration is highly variable for each offending agent. Third, the worker's clinical features should be consistent with the syndrome related to this exposure. Fourth and final, there should be no other more likely explanation for the clinical manifestations. The last criterion is important because tobacco smoking and other cardio-respiratory illnesses may be equally prevalent in these persons. Other more specific criteria have also been proposed for disorders, such as asbestosis and beryllium lung disease.

Patient evaluation generally begins with a review of type and frequency of the respiratory symptoms. The timing or periodicity of symptoms in relation to occupational exposure is important. All jobs of the patient, from the first to the current, should be looked into, especially for diseases related to chronic exposures. If any significant occupational exposure is found, one should determine (a) the type, amount and duration of exposure, (b) whether there is any time relationship to work or exposure and (c) if the exposure still continues. In addition, the patient should be asked whether ventilation at workplace was adequate and whether any personal protective gear (such as mask) was provided. It is also important to ask if other co-workers have been similarly affected. A complete physical examination should be conducted to detect manifestations of disease and also to identify any complications related to chronic lung disease (such as cor pulmonale).

The usual first investigation is chest radiograph. If available, the chest radiographs should be compared to the previous films. Hyperinflation and other findings consistent with airflow disorders should be noted. If radiographic abnormalities are rather diffuse, then the type and location of these opacities should be described. The radiological severity can be graded from mild to severe, as suggested by the International Labour Organization guidelines (**Table 1**). Computed tomography of chest may also be appropriate for a more detailed evaluation of pleural abnormalities, intrathoracic lymphadenopathy, lung nodules and interstitial disorders. Lung function studies should be performed on all patients, as they provide useful information on the functional status. Single breath diffusing capacity can be estimated for patients with exposure to fibrogenic dusts or exposure resulting in a diffuse infiltrative process and in patients with breathlessness out of proportion to radiologic manifestations.

ACUTE INHALATION INJURY

Although most occupational lung disorders result from prolonged exposures, it is important to recognise that short-term exposures can also be associated with pulmonary manifestations. Inhalation fever and acute toxic injury are the two prototypes of such disorders.

Inhalation Fever

Inhalation fever refers to an acute, self-limiting flu-like syndrome occurring after a single massive exposure to the offending agent. The illness resembles a viral flu and is marked by fever, chills, myalgia and malaise. Symptom onset is rather acute, typically 4 to 8 hours after initial exposure. Common precipitants include: (a) metal fumes (causing metal fume fever); (b) organic dusts and other bioaerosols contaminated with micro-organisms and endotoxins and/or mycotoxins, (causing the organic dust toxic syndrome); and (c) fumes produced by heating plastics (causing polymer fume fever).

Table 1: International Labour Organization Radiographic Classification of Pneumoconiosis

Small opacities (<10 mm in diameter) are defined by their average shape, size and profusion as recorded from standard chest radiographs.

Shape and Size	
Rounded (nodular)	*p* for diameters up to 1.5 mm *q* for diameters >1.5 mm but <3 mm *r* for diameters >3 mm but <10 mm
Irregular (reticular)	*s* if fine *t* if medium *u* if coarse
Profusion	
Category 0	small opacities are absent or less profuse than in category 1
Category 1	small opacities are present but few in number
Category 2	small opacities are numerous
Category 3	small opacities are more numerous with obscure normal radiographic markings

Conglomeration or coalescence of these opacities to produce one or more opacities with diameters greater than 10 mm defines 'complicated' pneumoconiosis or progressive massive fibrosis (PMF). This is categorised based on the size of large opacities (>10 mm in diameter):

Category A	sum of diameters of lesions is not more than 50 mm
Category B	total area occupied by lesions is not greater than the area of the right upper lobe (RUL)
Category C	total area occupied by lesions is greater than the area of the RUL

The intensity of these reactions may be dose-dependant. Pathologically, there is an intense non-allergic neutrophilic pulmonary inflammation. Overall, there is no significant structural damage to the respiratory tract. Peripheral leucocytosis is common. However, chest radiographs and pulmonary function tests typically remain normal. Treatment is largely supportive.

Acute Toxic Injury

Inhalation of irritant or toxic gases, vapours, particulates or aerosols may sometimes cause more severe injury to the respiratory tract. Such exposure can occur in almost any occupation. For instance, various respiratory irritants and asphyxiants can be encountered in mining environments. These include carbon dioxide, carbon monoxide, hydrogen sulphide, methane, nitrogen oxides, and sulphur dioxide. Pulmonary responses to these exposures are variable, and depend upon several factors that include: (a) solubility of substance; (b) particle size; (c) concentration; (d) duration of exposure; (e) chemical properties; and (f) host factors, such as minute ventilation of the exposed individual. Depending on the nature of the offending chemical and the intensity of the exposure, affected persons may develop rhinitis, pharyngitis, laryngitis, tracheobronchitis, bronchiolitis and/or pneumonitis. Compounds that are more water-soluble dissolve easily in the aqueous phase of mucous of the upper respiratory tract and airways, and cause maximal injury in these regions. This results in oedema and ulceration of the nasal passage, posterior oropharynx and larynx. The less water-soluble agents tend to bypass the upper airways and predominantly injure smaller airways and/or the lung parenchyma. With more severe injury, acute respiratory distress syndrome (ARDS) or organising pneumonia with obliterating bronchitis may occur.

Treatment is largely supportive. All victims should be removed from the site of exposure as early as possible. Supplemental oxygen, systemic corticosteroids and bronchodilators are usually prescribed. Patients need to be observed closely for any need for airway protection. If required, early airway intubation may be necessary to prevent the airway from acute laryngeal obstruction. Patients progressing to ARDS will require assisted ventilatory support. Following recovery from the respiratory injury, some patients may have persistent bronchial hyperreactivity manifesting as chronic cough.

COAL WORKER'S PNEUMOCONIOSIS

The development of pneumoconiosis among coal mine workers results from prolonged inhalation and deposition of carbonaceous dust. Dust exposure varies in different parts of the coalmine and is heaviest at the coalface.

Pathology

There are two major categories of coal worker's pneumoconiosis. Simple coal worker's pneumoconiosis is characterised by accumulation of small aggregations of carbon particles, uniformly distributed throughout both the lungs. These lesions (coal macules or coal nodules if large), consist of stellate aggregation of dust and dustladen macrophages around respiratory bronchioles with reticulin fibres and variable amounts of collagen. Complicated coal worker's pneumoconiosis [or progressive massive fibrosis (PMF)] is characterised by the presence of larger (usually more than 1 cm) anthracotic and fibrotic masses in pulmonary parenchyma. These lesions are typically situated in upper lobes, and may cavitate due to ischaemic necrosis.

Clinical and Radiographic Features

Simple coal worker's pneumoconiosis may not be associated with significant clinical symptoms or signs. It often gets detected as micronodular mottling on routine chest imaging. The disorder itself is not disabling, but may progress to complicated coal worker's pneumoconiosis. In contrast to simple coal worker's pneumoconiosis, complicated coal worker's pneumoconiosis is often associated with breathlessness, premature disability, pulmonary function abnormalities and reduced life expectancy.

Coal workers with rheumatoid arthritis may also develop multiple necrobiotic lung nodules up to 2 cm in diameter, often accompanied by subcutaneous rheumatoid nodules. This combination is referred to as Caplan's syndrome. In addition to pneumoconiosis, coal dust exposure increases a miner's risk of developing chronic obstructive pulmonary disease, especially among tobacco smokers. Because coal miners are often also exposed to varying amounts of silica, many patients present with a picture of mixed pneumoconiosis (often termed as anthracosilicosis).

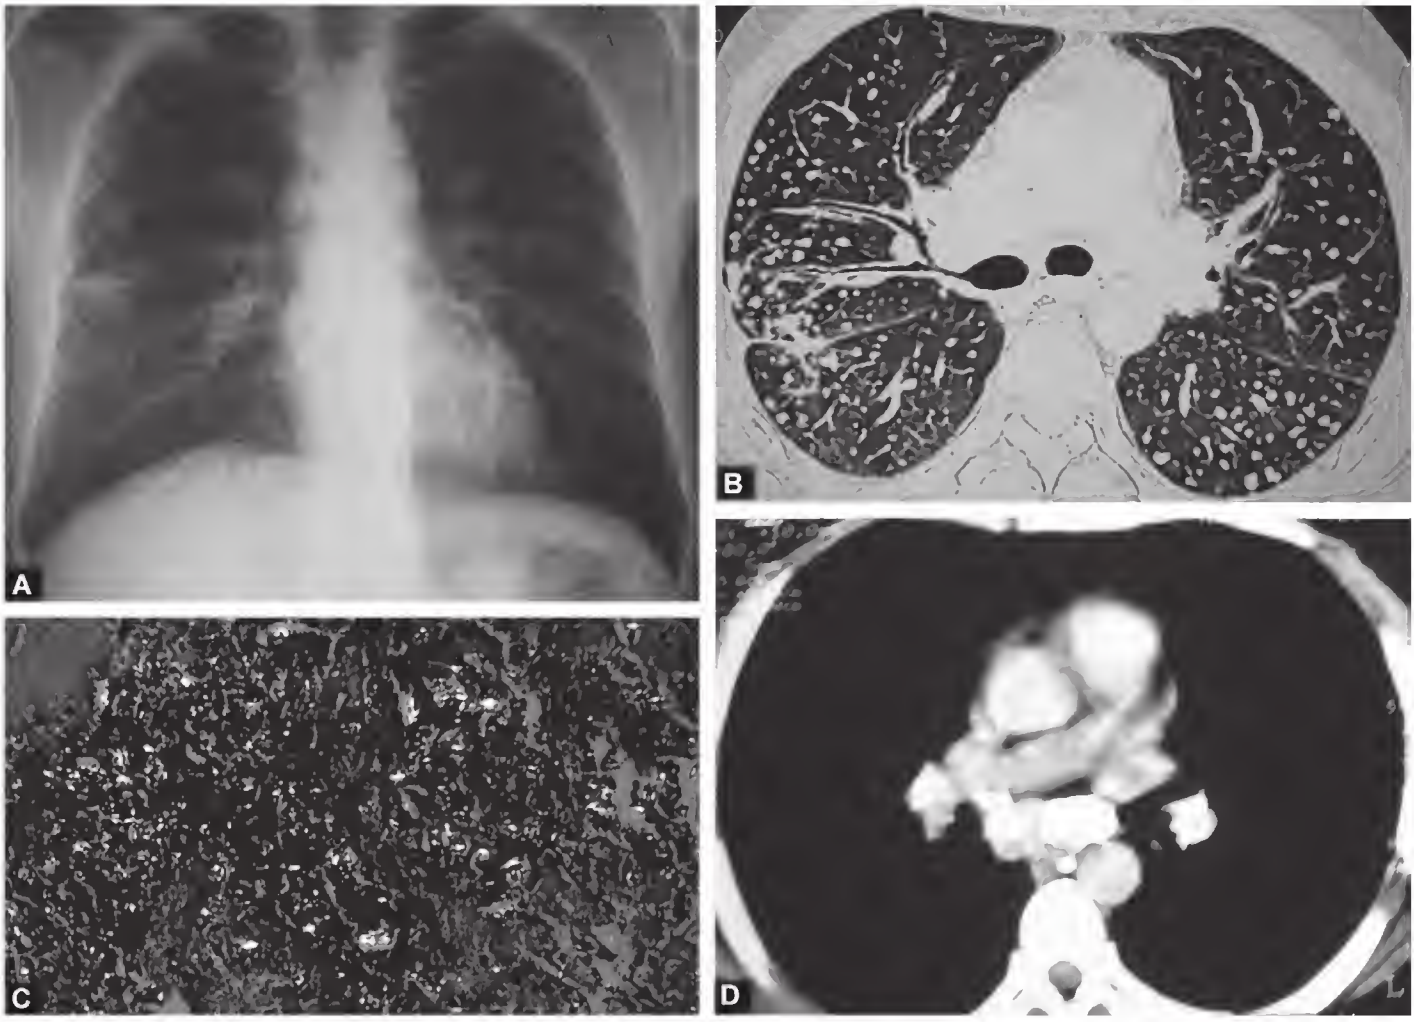
Treatment

There is no specific treatment for coal worker's pneumoconiosis. Prevention, early recognition and treatment of complications (such as airflow limitation, respiratory infections, respiratory failure, cor pulmonale or pneumothorax) remain the cornerstones of medical management.

SILICOSIS

Silicosis is a fibrotic disease of the lungs produced by inhalation and deposition of dust containing free crystalline silica (or silicon dioxide). The importance of silica as a health hazard is due to its ubiquity. Clinically significant exposures can occur during mining, quarrying, and tunnelling of granite or rock with high quartz content. Other industries at risk include sandblasting, manufacture of abrasive detergent, pottery making, brickworks, foundry work, jade polishing, etc.

Pathogenesis



The exact mechanism of lung injury after silica inhalation remains unclear. Alveolar macrophages engulf inhaled free silica, get activated and release cytokines growth factors and oxidants. This stimulates pulmonary parenchymal inflammation, and ultimately leads to fibrosis. Since silica particles cannot be biologically degraded, they outlive the macrophages that ingest them and continue the cycle of lung damage.

Clinical and Radiographic Features

Silicosis can manifest acutely after extreme exposure, but usually manifests in a chronic form requiring many years to develop.

Acute silicosis, and the less common accelerated silicosis, is caused by intense silica dust exposure over short periods (up to two years). In the acute form, mononuclear cells infiltrate alveolar septa, and alveolar spaces fill up with a acellular proteinaceous material. The overall clinical and pathological profile is quite similar to pulmonary alveolar proteinosis, and the condition is often referred to as silicoproteinosis. Severe hypoxaemia is common and hence, this condition is potentially life-threatening.

Chronic silicosis is usually diagnosed after several years of silica exposure. In the initial phase, patients may have no obvious symptoms or may have non-specific, respiratory symptoms. Cough and dyspnoea are common. Radiologically, there is a profusion of small (and typically rounded) opacities predominantly in upper lung fields (**Figures 1A to D**). Enlarged hilar and mediastinal lymph nodes, with a characteristic egg-shell calcification, are common. With continued exposure and disease progression, lung nodules coalesce to form larger masses, and fibrosis and bullae formation set in. This phase is termed as

Figures 1A to D: (A) A typical chest radiograph (postero-anterior view) from a patient with silicosis, showing small round nodules and patchy areas of fibrosis. (B) These features are better appreciated on a chest CT. (C) Histopathological examination of a bronchoscopic lung biopsy specimen under polarised light shows birefringent silica particles within fibrotic nodules. (D) Calcified hilar and mediastinal nodes are also seen on chest CT.

progressive massive fibrosis and is clinically associated with significant lung function impairment and more severe symptoms.

Patients of silicosis are at an increased risk of mycobacterial disease (both typical and atypical), possibly due to functional defects in alveolar macrophages. More recently, silica has also been recognised as a potential human carcinogen.

Treatment

Patients with acute silicosis require oxygen therapy and in severe cases, mechanical ventilation. Whole lung lavage may be beneficial in silicoproteinosis. There is no specific treatment for chronic silicosis and supportive measures need only be prescribed. Patients must be removed from their workplace to prevent further worsening of the disease.

ASBESTOS-RELATED LUNG DISEASE

Asbestos is a collective term for naturally occurring fibrous mineral silicates, widely used for their insulation and fire resistant properties. Major exposures occur during asbestos mining, manufacture/installation of thermal insulation for ships and power stations, production of brake and clutch linings, etc.

Pathogenesis

Asbestos fibres are either serpentine (e.g. chrysotile) or straight (e.g. crocidolite, amosite, tremolite). The former are more commonly used, but the latter penetrate deeper into lungs and are more resistant to breakdown. In contrast to other pneumoconioses, asbestos-related diseases can occur in people with very small or casual exposure as well, and have a latent period of several decades.

Small fibres get deposited in the wall of respiratory bronchioles and are phagocytosed by the macrophages. In contrast for other mineral dust particles, the long asbestos fibres are difficult for macrophages to engulf. The activated macrophages secrete cytokines and chemical mediators of inflammation, which in turn damage the lung parenchyma and lead to fibrosis.

Clinical and Radiological Features

Asbestosis refers to progressive diffuse lung fibrosis resulting from prolonged asbestos exposure. Once initiated, the damage progresses irrespective of removal from continued exposure. Clinical and radiological features resemble those to other interstitial lung disorders with cough, breathlessness, bibasilar crepitations, finger-clubbing and restrictive ventilatory defects being common. Presence of pleural thickening and diaphragmatic or pericardial calcification are useful radiographic findings. Asbestos bodies (asbestos fibres coated with iron-rich protein) may be demonstrated on microscopy from areas of fibrosis.

Pleural manifestations are also common. Benign effusions have the shortest latency (often less than ten years) and may be recurrent. They are typically small and unilateral exudates. Pleural plaques are the commonest radiographic marker of asbestos exposure. Non-calcified plaques are often seen along the chest wall or diaphragm and may be multiple and/or bilateral. They can enlarge to form sheets that get calcified later but are different from the diffuse pleural thickening often associated with lung parenchymal lesions. Persons with asbestos exposure are at a considerably higher risk to develop pleural mesotheliomas, as well as other malignancies involving lung, gastrointestinal tract and kidney (see chapter 1, section 27 also).

OCCUPATIONAL ASTHMA

Asthma is a common occupational disease and may be defined as variable airway obstruction due to a sensitising agent inhaled at workplace. It is common among spray painters, bakers, hairdressers and workers in chemical industries. Typically, asthma-like symptoms occur only at work or immediately thereafter and improve over weekends and during vacations. With continued exposure, however, symptoms may become chronic and loose the obvious relation to workplace exposure. A significant change in forced expiratory volume in one second across work shift is highly suggestive. Lung function testing with specific inhalational challenge to suspected workplace agents may help identify the causative agent. Timely removal from further exposure (e.g. change of job) is helpful in controlling symptoms, especially in the early phase of the disease. Disease control strategies remain otherwise similar to those for non-occupational asthma.

HYPERSENSITIVITY PNEUMONIA

Hypersensitivity pneumonia is also termed as extrinsic allergic alveolitis. It is an inflammatory disorder of the lungs which involves alveolar walls and terminal airways. It is induced in patients by inhalation of certain toxic agents (allergans). The host susceptibility and the allergans, of the organic substances are responsible for subacute or acute pneumonia. The common conditions are farmer's lung, allergic broncopulmonary aspergillosis and others. The hypersensitivity pneumonia are influenced by the weather conditions and the presence of allergans in the atmosphere.

23.14 Sarcoidosis

VK Vijayan

INTRODUCTION

Sarcoidosis is a systemic disorder of unknown origin characterised by granulomatous inflammation in a variety of organs, most commonly, the lung and affects people of all racial and ethnic groups. Though thought to be uncommon earlier, sarcoidosis cases are increasingly being reported from India during the second half of the last century. This may be due to the increasing awareness of physicians to the clinical entity and also the availability of new diagnostic tools such as thoracic imaging including computed tomography (CT), pulmonary function testing, fibre-optic bronchoscopy and immunological investigations. However, the accurate diagnosis of sarcoidosis and the ability to differentiate it from tuberculosis (TB) are challenges to physicians, especially in countries with high prevalence of TB.

EPIDEMIOLOGY

Sarcoidosis occurs worldwide. It affects persons of all races and both sexes with a wide range of prevalence (1 to 40/100,000). The highest prevalence (>50/100,000) has been reported in Scandinavian countries and the United States (US) African-American population. It appears to be less frequent in Asian countries, South America and Africa but is common in Japan, USA and central Europe. Globally, sarcoidosis shows a predilection for young adults (<40 years) with a slight female predominance and it is rare in children. However, it can occur at all age groups. Socio-economic status does not affect the risk of sarcoidosis. In contrast to Western data, sarcoidosis in India has a later onset by a decade and the disease is more common in men.

AETIOLOGY

The aetiology of sarcoidosis is unknown. It has been suggested that sarcoidosis results from the exposure of genetically susceptible individuals to specific environmental agents. Several studies strongly suggested that the disease could spread by person-to-person transmissions or shared exposure to an environmental agent. An increased incidence of sarcoidosis has been reported in rescue workers from the New York City Fire Department involved in the 2001 World Trade Centre disaster. Mycobacterial and propionibacterial deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) have been recovered from sarcoid tissues. Several non-infectious agents and micro-organisms have been implicated as possible aetiological agents of sarcoidosis (**Table 1**). However, there is no definite proof that any of these agents is involved in the aetiology of sarcoidosis. It has been suggested that sarcoidosis is an end result of immune responses to various ubiquitous environmental triggers. The incidence of sarcoidosis has been reported to be higher in non-smokers. It has also been suggested that sarcoidosis is an autoimmune disease.

Genetic susceptibility to sarcoidosis involves several genes but no single gene responsible for the disease has been demonstrated. Polymorphism of tumour necrosis factor-α (TNF-α) gene, interleukin-1 (IL-1) gene, angiotensin converting enzyme (ACE) gene, and vitamin D receptor gene has been reported to be associated with the expression of the disease. Human leukocyte antigen (HLA) DQB*0602 appears to be associated with progression of disease. HLA DR 11, 12, 14, 15 and 17 appear to confer susceptibility to disease and HLA DR1, DR4 and HLA DQ*0202 seems to be protective.

Table 1: Aetiological Agents Postulated for Sarcoidosis

Infective agents
Viruses
Epstein-Barr virus
Retroviruses
Coxsackie B virus
Cytomegalovirus
Herpes virus
Bacteria
Propionibacterium acnes
Borrelia burgdorferi
Mycobacterium tuberculosis
Cell wall deficient mycobacteria and other mycobacteria
Mycoplasma
Chlamydia
Nocardia
Occupational and environmental exposure
Beryllium
Zirconium
Aluminium
Talc
Pine tree pollen
Clay soil

PATHOGENESIS

The development of sarcoidosis requires three major events: exposure to antigen; acquired cellular immunity directed against the antigen mediated through antigen-presenting cells and antigen-specific T-lymphocytes; and the appearance of the immune effector cells that promote a non-specific inflammatory response (granulomatous inflammation). The characteristic feature of sarcoidosis is the non-caseating granuloma formation. The CD4+ T-cells interact with antigen-presenting cells and initiate granuloma formation. The CD4+ T-cells on activation differentiates into type 1 helper T (Th1)-like cells that secrete IL-2 and interferon-γ and induce macrophages to produce TNF-α production. It has been reported that serum amyloid A regulates granulomatous inflammation in sarcoidosis through toll-like receptor-2. Granulomas contain central collection of macrophages and epithelioid cells surrounded by lymphocytes. Macrophages differentiate into epithelioid cells which fuse to form multi-nucleated giant cells. The granulomatous response resolves during the following 2 to 5 years in more than 60% of patients.

However, it has not been clearly understood why lung disease persists and leads to pulmonary fibrosis in some patients but not in others. Though the pathogenesis of lung fibrosis in sarcoidosis is unknown, it has been observed that there is an increase in matrix metalloproteinases 8 and 9 in bronchoalveolar lavage and sputum specimens from patients with sarcoidosis. It has been postulated that uninhibited protease activity initiates extracellular matrix breakdown and remodelling.

PATHOLOGY

Sarcoid granulomas can be seen in the lung, lymph nodes, mucus membranes, liver, myocardium, central nervous system, skin, joints, and parotid glands. These granulomas are non-caseating, discrete, tight, and compact and may contain inclusion bodies such as Schumann, asteroid, Hamazaki-Wesenberg or crystalline bodies. Unlike tuberculous granulomas, reticulin fibres are preserved in sarcoid granulomas (**Figure 1**). Spontaneous resolution of granulomas can occur in 70% to 90% of the Caucasian subjects and 10% to 15% patients progress to irreversible fibrosis. In the lungs, the granulomas are located close to or within connective tissue sheaths of the bronchioles, subpleural and perilobular spaces and small vessels (a lymphangitic distribution). Granulomata in the lung biopsy specimens have been demonstrated in up to 80% of the patients with stage-I disease without radiological involvement of lung parenchyma.

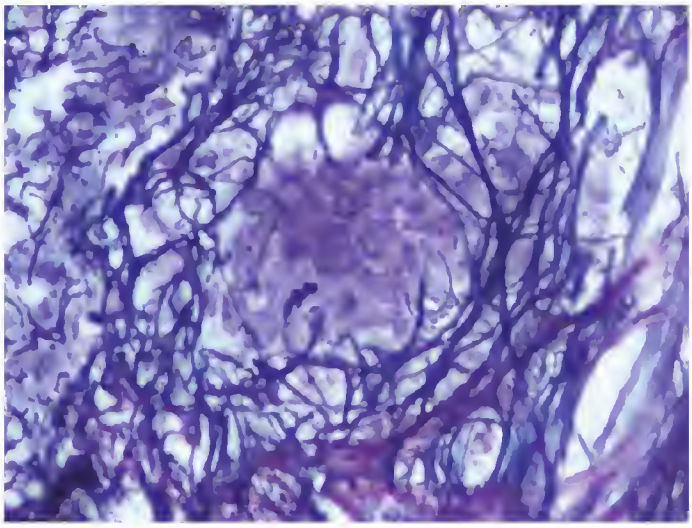

Figure 1: Reticulin surrounding the sarcoid granuloma.

CLINICAL FEATURES

Patients with sarcoidosis may present to different specialities as sarcoidosis is a multi-organ disorder. The clinical feature may vary depending on the ethnicity, duration of illness, site, and extent of organ involvement and activity of the granulomatous process. Many asymptomatic patients (30% to 50%) are discovered when a chest radiograph is obtained for screening purposes.

Constitutional symptoms such as fever, night sweats, fatigue and weakness, anorexia and weight loss have been found to be more common in Indian patients. Sarcoidosis is an unusual cause of fever of unknown origin. Sarcoidosis can present as acute or chronic disease. Acute presentations are frequently seen in Caucasians, and may present with Löfgren's syndrome (bilateral hilar lymphadenopathy, ankle arthritis, erythema nodosum and constitutional symptoms) or Heerfordt's syndrome (fever, parotid gland enlargement, facial palsy and uveitis). Acute sarcoidosis is uncommon in Indian patients. Chronic sarcoidosis has an insidious onset, constitutional symptoms are uncommon and symptoms are related to the organs involved. Pulmonary hypertension (PH) is an important complication of sarcoidosis in 6% to 23% of the patients. Pulmonary fibrosis leading to obliteration of the pulmonary vessels and granulomatous infiltration of the pulmonary arterioles are the proposed mechanisms of PH.

Lung Involvement

Lung manifestations are seen in almost all (>90%) patients. Predominant pulmonary symptoms (30% to 50%) are dyspnoea, dry cough and chest pain. Haemoptysis is rare, clubbing is not usually seen. Localised wheezing due to endobronchial segmental or lobar stenosis mimicking asthma can occur in up to 10% of the patients. Physical findings are observed in less than 20% of the subjects, dry rales are the most frequent signs.

Chest imaging

The chest radiographic findings are classified into four stages (**Table 2**). At the time of diagnosis, most of the patients in the West have stage-I disease whereas majority of the Indian patients present with stage-II disease (**Figure 2**). The characteristic chest radiographic finding is bilateral hilar lymphadenopathy. A 'clinico-radiological dissociation' in which the chest radiographic findings may appear widespread and frightening with minimal symptoms has been described in Indian patients with sarcoidosis.

Other chest radiographic findings include reticular, reticulonodular or focal alveolar opacities, areas of consolidation with air bronchograms, miliary mottling and ground-glass opacities. Calcified lymph nodes resembling egg-shell calcifications can occur in >5% patients with long-standing sarcoidosis. As fibrosis sets in, pleural adhesions to the diaphragm, bullae, cysts and honeycombing are observed in the end-fibrotic stage of the disease. Involvement of larynx, trachea and bronchi can lead to stridor, airway obstruction and bronchiectasis. Pleural effusion, pneumothorax and pleural thickening are uncommon findings. Nasal stuffiness and palatal obstruction or disfigurement from lupus pernio has been described. Contrast-enhanced computed tomography (CECT) demonstrates the lymphangitic distribution. The characteristic CECT findings are ground-glass attenuation (**Figure 3**), central bronchovascular thickening and nodularity (**Figure 4**), thickening of inter-lobular septae, miliary nodules, conglomerate masses, consolidation and architectural distortion, parenchymal and pleural nodules. Contrast-enhanced computed tomography also demonstrates paratracheal, hilar and mediastinal lymphadenopathy.

Table 2: Chest Radiographic Stages in Sarcoidosis

Stage	Finding	Frequency
0	Normal chest radiograph	5% to 10%
I	Bilateral hilar lymphadenopathy (BHL)	50%
II	BHL and pulmonary infiltrations	25%
III	Pulmonary infiltrations without BHL	15%
IV	Pulmonary fibrosis	5% to 10%

Figure 2: Chest radiograph (postero-anterior view) showing bilateral hilar lymphadenopathy and pulmonary infiltrates (stage II sarcoidosis).

Figure 3: CECT chest showing ground-glass attenuation.

Pulmonary functions and gas exchange

Pulmonary function test results are often normal in early stages. The main pulmonary function abnormalities in advanced disease are restrictive ventilatory defect and reduced diffusion capacity for carbon monoxide (DLCO). Airway obstruction is also observed when the bronchial mucosa is involved. Pulse oximetry is often normal when measured at rest but may show desaturation after exertion in patients with extensive lung involvement. Arterial blood gas analysis at rest and during exercise is more sensitive than pulse oximetry. Reversible airway obstruction mimicking bronchial asthma and airway hyper-reactivity have also been reported in Indian patients.

Bronchoscopy

Flexible fibre-optic bronchoscopy (FOB), transbronchial lung biopsy (TBLB), endobronchial biopsy, transbronchial needle aspiration, and bronchoalveolar lavage (BAL) are all useful to obtain tissue sample for the diagnosis of sarcoidosis. The bronchoscopic appearances of sarcoidosis are plaques, nodules, and erythema and cobblestone appearance. Bronchoalveolar lavage reveals lymphocytic alveolitis with an elevated CD4+/CD8+ ratio.

Figure 4: CECT chest showing nodular sarcoidosis.

Cardiac Sarcoidosis

In clinical series, cardiac dysfunction is uncommon (5% to 10%) compared with autopsy studies where a higher prevalence of cardiac sarcoidosis (76%) has been described. Granulomas and scars are commonly found in the left ventricular free wall and the interventricular septum with involvement of the conducting system. Cardinal cardiac manifestations include arrhythmias of all types, conduction abnormalities, congestive heart failure, and sudden death. Other cardiac manifestations include papillary muscle dysfunction, infiltrative cardiomyopathy and pericarditis. Doppler echocardiography may show cardiac dysfunction, especially diastolic dysfunction. Thallium-201 (^{201}Tl) scintigraphy shows segmental areas of decreased thallium uptake and this corresponds to granulomata or fibrosis. The perfusion defects in sarcoidosis decrease in size during exercise and this is in contrast to the findings in cardiac ischaemia ('reversed distribution'). Endomyocardial biopsy may be useful to demonstrate noncaseating granulomas in cardiac sarcoidosis.

Skin Involvement

Skin involvement is common (25%) and the cutaneous manifestations range from small purplish macules, papules to plaques, and subcutaneous nodules. Alopaecia and hypo- and hyper-pigmented areas are also noticed. Sometimes, sarcoidosis can occur in scars and tattoos. Erythema nodosum is a manifestation of acute sarcoidosis and usually lasts for about 3 weeks. Lupus pernio is an indurated, lumpy, violaceous lesion on the nose, cheeks, lips or ears and can be extremely disfiguring and may erode into underlying cartilage and bone.

Neurosarcoidosis

Neurological manifestations are rare (<10%) and include cranial nerve involvement (particularly facial nerve palsy) and hypothalamic and pituitary involvement. Other manifestations include headache, ataxia, cognitive dysfunction, weakness and seizures. Space occupying masses, peripheral neuropathy and neuromuscular involvement occur in chronic sarcoidosis.

Computed tomography and magnetic resonance imaging (MRI) with gadolinium are the diagnostic modalities in neurosarcoidosis. Cerebrospinal fluid examination reveals lymphocytes, elevated protein and increased ACE levels.

Ocular Sarcoidosis

Ophthalmic lesions are common (20% to 30%) and may sometimes be severe resulting in blindness. The most common manifestation is uveitis. Anterior uveitis manifests as painful red eye, blurred vision and light sensitivity and may cause periphlebitis which has been described as 'candle wax drippings'. Acute anterior uveitis usually clears spontaneously within a year or after local therapy with corticosteroids. Posterior uveitis requires systemic treatment. The chronic form of uveitis can lead to glaucoma, cataract and blindness. Conjunctiva can be involved as small, pale, yellow nodules. Keratoconjunctivitis sicca, retinal vasculitis, lacrimal gland enlargement and dacryocystitis are other ocular manifestations. Eye involvement may be asymptomatic and this emphasises the need for ophthalmic investigation including slit-lamp and fundoscopic examination in every patient with sarcoidosis.

Lymphoid System and Spleen

Intrathoracic and peripheral lymph node enlargement is common. Radiographic evidence of hilar lymph node enlargement is seen in up to 90% of the patients. Peripheral lymph nodes are enlarged in about one-third of the patients. Peripheral nodes are firm, discrete, mobile and non-tender. The spleen is frequently enlarged (40% to 80%) in autopsy studies, but clinical symptoms due to splenomegaly are rare. Splenic rupture (spontaneous or traumatic) is an unusual complication of massive splenomegaly.

Hepatic and Gastrointestinal Sarcoidosis

Clinically significant hepatic dysfunction is rare. Liver is palpable in only up to 20% of the patients. However, liver biopsy had revealed granuloma in up to 80% of the patients. Cholestatic pattern of biochemical alterations with minimal increase in aminotransferase concentrations are seen in up to one-third of the patients and manifest as pruritus and jaundice. Occasionally severe disease leading to intra-hepatic cholestasis, portal hypertension and hepatic failure has been reported. Variceal bleeding due to portal hypertension, hepatopulmonary syndrome with refractory hypoxaemia and cirrhosis has been reported in hepatic sarcoidosis in nearly 1% of the patients. The gastrointestinal tract is rarely involved (<1%); the stomach is the commonly involved organ. Other parts involved are oesophagus, appendix, rectum and pancreas.

Renal and Endocrine Systems

The enzyme, 25-hydroxyvitamin D-1α- hydroxylase present in the sarcoid macrophages converts 25-hydroxyvitamin D to 1, 25-dihydroxyvitamin D. The overproduction of 1, 25-dihydroxyvitamin D causes increased intestinal absorption of calcium and enhanced bone resorption leading to hypercalciuria with or without hypercalcaemia. This can result in nephrocalcinosis, urolithiasis and renal failure. Kidneys can also be involved directly by a granulomatous interstitial nephritis. Diabetes insipidus may occur due to the involvement of hypothalamus or pituitary glands. Rare endocrine manifestations include hypothyroidism, hyperthyroidism, hypothermia, anterior pituitary gland involvement and adrenal suppression.

Musculoskeletal Manifestations

Arthralgias are more common (25% to 39%) than arthritis in Indian patients. Acute arthritis is rare in Indian patients. Knees, ankles, elbow, wrists and small joints of hands and feet are involved. Muscles can be involved leading to proximal muscle weakness and this has to be differentiated from corticosteroid-induced myopathy.

Other Manifestations

Painless unilateral or bilateral enlargement of the parotid gland (~15%), cystic bone lesions associated with chronic skin lesions, anaemia (4% to 20%), and leucopaenia (40%) are also described. The erythrocyte sedimentation rate (ESR) may be moderately raised. Hypergammaglobulinaemia is common with raised immunoglobulin (Ig)G levels. Other uncommon manifestations reported from India are cirrhosis of liver with portal hypertension, superior vena cava syndrome, breast lumps and transient paralysis of phrenic and recurrent laryngeal nerves. Sarcoid granulomas can also be seen in breast and uterus.

DIAGNOSIS

The diagnosis of sarcoidosis is based on the following criteria: a compatible clinical and/or radiological picture; histological evidence of non-caseating granulomas; and exclusion of other diseases that produce similar histological or clinical picture. Tuberculin skin test (up to 100 TU) is negative in about 60% cases. Sarcoidosis, poses a great diagnostic challenge to physicians in countries where the prevalence of TB is high. If the tuberculin skin test is positive, the diagnosis of TB should be seriously considered in suspected cases of sarcoidosis from countries with high prevalence of TB.

Recommended tests for evaluation of patients with sarcoidosis are listed in **Table 3**. Clinical presentation and thoracic imaging studies may suggest the diagnosis of sarcoidosis. All suspected cases should be confirmed by biopsy to exclude infections or malignant conditions. FOB with TBLB are recommended in most cases as the diagnostic yield is high (80% to 90%), if 4 to 5 samples are obtained. Histological demonstration of granuloma is also possible by bronchial mucosal biopsy even when bronchial mucosa is normal (40% to 60%) and the yield may exceed 90% when there are gross endoscopic findings, such as mucosal nodularity, oedema, or hypervascularity. Bronchoalveolar lavage is a research tool and may help in excluding other causes, such as infectious aetiology.

Other sites for biopsy are visible skin lesions, the lips, and the conjunctiva or enlarged superficial lymph nodes, liver (if serum alkaline phosphatase is elevated). If bronchoscopic procedures or biopsies from other sites have failed to provide a diagnosis, mediastinoscopy, video-assisted thoracoscopic surgery (VATS) or open lung surgery is done occasionally to obtain tissue samples mainly to exclude other intrathoracic disorders.

The presence of non-caseating granulomas on biopsy should not be taken as confirmation of the diagnosis of sarcoidosis. Other granulomatous diseases, especially TB should be excluded to make a diagnosis of sarcoidosis (**Table 4**). In patients with the classical Löfgren's syndrome, biopsies are not usually necessary. Gallium-67 (^{67}Ga) scanning may demonstrate a lambda pattern (uptake in bilateral hilar and right paratracheal lymph nodes) and a 'panda pattern' (uptake in parotid and lacrimal glands).

^{18}F-fluorodeoxyglucose (^{18}F-FDG) positron emission tomography (PET) appears to be more accurate and contribute to a better evaluation of extrapulmonary sarcoidosis. Cardiac MRI with gadolinium enhancement and PET have been found to be useful in the diagnosis of cardiac sarcoidosis. Serum ACE activity has no diagnostic value. The Kveim-Siltzbach skin test is not widely available. In addition, difficulties in standardisation and risks of transmissions of infective diseases limit its usefulness.

Table 3: Diagnostic Methods for the Evaluation of Patients with Sarcoidosis

History (occupational and environmental exposure; symptoms)
Physical examination with emphasis on lung, skin, eye, liver, heart, and nervous system
Peripheral blood counts (white blood cells, red blood cells, platelets)
Serum chemistry (calcium, liver enzymes, creatinine, blood urea nitrogen, and angiotensin converting enzyme)
Urine analysis
Chest radiograph (postero anterior view)
High resolution computed tomography (HRCT) and CECT of chest
^{18}F-FDG PET in patients without apparent lung involvement to identify the sites for diagnostic biopsy
^{18}F-FDG PET and MRI with gadolinium to detect cardiac and neurologic involvement
Pulmonary function tests (spirometry, lung volumes, carbon monoxide diffusing capacity and arterial blood gases at rest and after exercise)
Tuberculin skin test
Electrocardiogram (ECG)
Ophthalmic evaluation with slit-lamp examination
Biopsy to obtain histologic confirmation of non-caseating granulomas (with special stains and cultures to exclude tuberculosis, fungal diseases, and malignancy)
Fibre-optic bronchoscopic procedures including bronchoalveolar lavage
Biopsy from skin, lip, lymph node or granulomatous scar
Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), open lung biopsy
Other tests depending on clinical presentation and suspicion of extrathoracic disease

^{18}F-FDG PET = ^{18}F-fluorodeoxyglucose positron emission tomography, MRI = Magnetic resonance imaging.

Table 4: Causes of Granulomatous Lung Diseases Other than Sarcoidosis

Infective agents	**Disease**
Mycobacteria	Tuberculosis, atypical mycobacterial infection
Fungi	Histoplasmosis, coccidioidomycosis
Bacteria	Brucellosis, chlamydia infection, tularaemia
Spirochetes	Treponemal infections
Parasites	Leishmaniasis, toxoplasmosis
Occupational and environmental exposure	
Organic or inorganic agents	Hypersensitivity pneumonitis
	Chronic beryllium disease
	Talc
	Granulomatous disease related to other metals (titanium, aluminium, and zirconium)
	Methotrexate pneumonitis
Other conditions	
Neoplasia	Lymphoma, tumour-related granulomas
Autoimmune disorders	Wegener's granulomatosis, primary biliary cirrhosis, Churg-Strauss syndrome

ASSESSMENT OF ACTIVITY

Though many laboratory and serological markers have been described to assess the activity of sarcoidosis, none of them is useful in clinical practice. Clinical evaluation of the patients based on the mode of onset, the worsening or presence of symptoms and the presence of skin lesions in association with changes in chest radiograph and lung function tests is the best way to assess the activity of sarcoidosis.

TREATMENT

Asymptomatic patients with normal lung function and patients with minimal, well tolerated symptoms and mild functional abnormalities should be observed without treatment because of the potential for spontaneous improvement. These patients require treatment only if symptom develops or lung function deteriorates. The aim of the treatment is prevention of the irreversible loss of organ function and improvement of symptoms for better quality of life. Patients with symptoms can be treated with corticosteroids. Severe ocular, neurosarcoidosis, cardiac sarcoidosis, malignant hypercalcaemia, symptomatic, and/or progressive stage-II and stage-III pulmonary disease require treatment with oral corticosteroids as the first-line treatment. Though corticosteroid therapy may have short-term benefits, there is no evidence that these improve long-term outcome. Pulmonary sarcoidosis is treated with prednisolone (30 to 40 mg/day, gradually tapered to 5 to 10 mg/day over 2 to 3 months). The treatment should be continued for a minimum duration of 12 months. In order to decrease the side effects of hypothalamic suppression, alternate day treatment using equivalent total dosages of prednisolone is also effective. Cardiac or neurological sarcoidosis requires higher doses of steroids. Löfgren's syndrome can be treated with non-steroidal anti-inflammatory drugs. Several patients (~25%) relapse after discontinuation of corticosteroid therapy and some with repeated relapses may require indefinite therapy. Inhaled corticosteroids may reduce symptoms in endobronchial sarcoidosis, but its role in parenchymal sarcoidosis is not well established. Topical steroids have also been found to be useful in some patients with skin sarcoidosis, nasal involvement, or iritis/uveitis.

ALTERNATIVE TREATMENTS

Patients with sarcoidosis requiring long-term corticosteroid therapy and suffering from major side effects of steroids can be offered steroid-sparing alternative treatments. These agents can be used in combination with reduced dosages of steroids or can also be given as a single therapy. Prednisolone requirement has been found to be considerably reduced in patients receiving methotrexate (10 to 25 mg weekly) for six months. Hepatitis and neutropaenia are important adverse effects of methotrexate therapy. Other cytotoxic drugs for sarcoidosis are azathioprine (100 to 150 mg/day) and cyclophosphamide (50 to 150 mg/day). The antimalarial drugs chloroquine and hydroxychloroquine (200 to 400 mg/day for 6 months) have been found to be useful in lupus pernio, nasal sarcoidosis, disfiguring skin sarcoidosis and hypercalcaemia. As hydroxychloroquine is found to be less toxic, it can be used for prolonged periods without retinal damage. Chloroquine has also been reported to be useful in chronic pulmonary sarcoidosis and also in neurosarcoidosis failed on corticosteroid treatment. Other investigational drugs for treatment of

sarcoidosis are minocycline, pentoxifylline, thalidomide, and specific TNF-α inhibitors (etanercept, infliximab). There is an increased risk of TB with infliximab treatment. Patients with end-stage sarcoidosis and cor pulmonale require supplemented oxygen, diuretics, and bronchodilators to relieve airway obstruction. In the end-stage disease, lung transplantation has been successfully performed. Recurrent sarcoidosis has been reported in the lung allograft. However, it is not clinically or radiologically significant.

NATURAL HISTORY AND PROGNOSIS

Sarcoidosis is considered as a benign disease with a tendency to wax and wane either spontaneously or in response to treatment. It has been reported that 60% to 70% of the patients have spontaneous remission and 10% to 30% of the patients have a chronic course. However, this may vary depending on geographical and ethnic differences. Permanent sequelae are seen in 10% to 20 % of the patients. Acute form of the disease (e.g. Löfgren's syndrome) has good prognosis. Mortality in sarcoidosis has been reported to be 1% to 5% and the most common cause of death is respiratory failure. However, the death can frequently be due to myocardial involvement. Adverse prognostic factors in sarcoidosis are lupus pernio, chronic uveitis, onset of disease after 40 years, chronic hypercalcaemia, nephrocalcinosis, black race, progressive pulmonary disease, nasal mucosal involvement, cystic bone lesions, neurosarcoidosis, myocardial sarcoidosis, symptoms that last for more than 6 months, the absence of erythema nodosum, splenomegaly, and involvement of more than three organs.

23.15 Sleep Related Breathing Disorders

R Narasimhan, AR Gayathri

INTRODUCTION

Sleep is a state of relatively suspended sensory and motor activity, which occurs naturally, is recurring and which is characterised by total or partial unconsciousness with the inactivity of nearly all voluntary muscles. One-third of our lives is spent in sleep. Any changes in the quantity, quality, or pattern of sleep may result in sleep disorders. Over the past 50 years, research into sleep disorders and the clinical advances have lead to more effective treatment of sleep disorders.

Sleep disorders are quite common but are frequently undiagnosed and untreated. The 2nd edition of the *International Classification of Sleep Disorders* (ICSD-2) was published by the American Academy of Sleep Medicine in 2005. This classifies sleep disorders into eight major categories: (1) insomnia, (2) sleep-related breathing disorders (SRBD), (3) hypersomnias of central origin, (4) circadian rhythm sleep disorders, (5) parasomnias, (6) sleep related movement disorders, (7) isolated symptoms and (8) normal variants and other sleep disorders.

Sleep related breating disorders is a general term which includes both obstructive sleep apnoea (OSA) and central sleep apnoea (CSA). Obstructive sleep apnoea results from complete or partial upper airway obstruction, while CSA usually results from reduction in overall respiratory drive.

Apnoea means cessation of airflow for at least 10 seconds. Apnoea can be obstructive (respiratory effort without airflow), central (absence of both airflow and respiratory effort) or mixed. Hypopnoea is a reduction in airflow of 30% from a baseline for longer than 10 seconds and is associated with an oxygen desaturation of more than or equal to 4%. The apnoea-hypopnoea index (AHI), is the total number of apnoeas and hypopnoeas per hour of sleep. An aphoea-hyponoea index of more than 5 is indicative of OSA. The CSA syndrome is an AHI greater than 5 events per hour with more than 50% of the respiratory events classified as central rather than obstructive. Apnoea-hyponoea index is the most commonly used objective clinical measure of sleep apnoea severity.

OBSTRUCTIVE SLEEP APNOEA SYNDROME

Epidemiology

Sleep related breating disorders affects patients regardless of their social or ethnic background. Western data estimates the prevalence of OSA between 0.3% to 4 %, affecting 2% to 4 % of males and 1% to 2% of females, with a large number of individuals still undiagnosed. A population based study in Delhi, India estimated the prevalence of OSA at 2.4 % in males and 1.0% in females.

Pathophysiology

Obstructive speep apnoea is characterised by periodic episodes of complete or incomplete upper airway obstruction. There are three immediate sequelae of OSA that include intermittent arterial blood gas abnormalities, arousals, and large negative swings in intrathoracic pressure. These events result in activation of neurohormones, hypercoagulopathy, oxidative stress, release of inflammatory mediators which lead on to structural alterations of the cardiac chambers. There are a number of anatomic abnormalities associated with OSA like retrognathia, maxillary retropositioning, caudal displacement of hyoid bone, intra-nasal obstruction, macroglossia, enlarged or low placed soft palate, and enlarged lymphoid tissue around the upper airways. Genetic variations, like Pierre-Robinson syndrome, Treacher-Collins syndrome and Down's syndrome may lead to the development of OSA.

Obesity is a major risk factor for OSA, with the neck size being the strongest predictor of OSA. The neck circumference is correlated with the increased dimensions of the parapharyngeal fat pads . The larger upper airway soft tissue of men may be one of the factors contributing to the increased incidence of OSA in males as compared to females.

Clinical Presentation

The signs and symptoms of OSA are many and some of them are listed in **Table 1**.

Table 1: Signs and Symptoms of Obstructive Sleep Aphoea

Question	Yes/No
Snoring	Yes
Witnessed apnoea	Yes
Unrefreshing sleep	Yes
Waking up gasping for air	Yes
Nocturnal reflux	Yes
Nocturia	Yes
Nocturnal sweating	Yes
Sleep talking	Yes
Morning dry mouth	Yes
Morning headache	Yes
Unexpected sleep onset	Yes
Falling asleep while driving	Yes
Routine napping	Yes
Unrefreshing naps	Yes

CARDIOVASCULAR CONSEQUENCES OF OBSTRUCTIVE SLEEP APNOEA

Hypertension

The prevalence of hypertension is greater in patients with OSA and hypertensive patients have higher incidence of OSA. The Wisconsin Sleep Cohort study showed the dose-response association between sleep disordered breathing at baseline and the development of new hypertension 4 years later.

Obstructive Sleep Apnoea and Coronary Artery Disease

Sleep apnoea events induce a state of increased oxygen demand as well as a state of low oxygenation reserve because of the lack of ventilation. This leads to a situation that nocturnal

angina can be triggered by apnoea in Coronary artery diseases (CAD) patients. Coronary artery diseases has been found to be present in one-fourth of OSA patients, with the percentage of patients with CAD being high in patients with moderate to severe OSA. Patients with CAD and nocturnal angina should be considered for sleep study because nasal continuous positive airway pressure (CPAP) reduces nocturnal angina attacks and nocturnal myocardial ischaemia.

Obstructive Sleep Apnoea and Left Ventricular Systolic Dysfunction

The Sleep Heart Healthy Study analysed the association between OSA and various cardiovascular disorders. It was found that an AHI >11 increased the risk of congestive cardiac failure by 2.38%. Haemodynamic, neurohumoral, inflammatory and oxidative stress, endothelial dysfunction and prothrombotic mechanisms are implicated in the development of left ventricular (LV) dysfunction in patients with OSA. The inter-mittent hypoxia caused by apnoea, followed by post apnoea reoxygenation contributes to generation of oxygen free radicals. This causes oxidative stress on the myocardial muscle fibres and plays a role in the development of systolic LV dysfunction. It has also been noted that the proportion of CSA increases from the first to the last quarter of the night.

Obstructive Sleep Apnoea and Arrhythmias

The most frequent arrhythmias seen in OSA are brady-arrhythmias. These include sinus bradycardia, atrioventricular block, complete heart block and ventricular asystole. These bradyarrhythmias are often asymptomatic, as the rhythm disturbances occur only at night. A strong association between OSA and atrial fibrillation has been found and this appears to be independent of gender, hypertension, heart failure or body mass index. Tachyarrhythmias, like ventricular and supra-ventricular tachycardia may occur in OSA.

Obstructive Sleep Apnoea and Stroke

Prospective cohort studies have demonstrated that OSA is associated with a two- to three-fold increased risk of developing a stroke, independent of known cerebrovascular risk factors.

Obstructive Sleep Apnoea and Pulmonary Hypertension

Hypoxaemia and apnoea cause acute elevations in pulmonary artery pressure during sleep but not all pulmonary hypertension can be solely attributed to OSA.

Sleep-Related Breathing Disorders in Pregnancy

The state of pregnancy, till recently, had been considered to be protective against the development of SRBD. Progesterone, though initially causes increased upper airway muscle activity, when primed with repetitive hypoxia, causes the reverse to occur. Progesterone also causes reduction in integrity of vascular endothelium leading to tissue oedema. The increased levels of circulating estrogen associated with pregnancy, cause vascular relaxation, especially in the upper portion of the upper airways. These changes contribute to the development of OSA. A causal link between SRBD and the development of gestational hypertension has been found.

Classification of Central Sleep Apnoea

There are two general categories of CSA – Hypercapnic and Non-hypercapnic. Hypercapnic CSA results from decreased sensitivity of chemoreceptors superimposed on a loss of the voluntary 'wake drive', which results in overall reduction in respiratory drive. Clinically, this presents as alveolar hypoventilation syndrome, which include among others, the obesity–hypoventilation syndrome, neuromuscular failure, chronic narcotic use and idiopathic central hypoventilation (Ondine's curse). These patients are chronic carbon dioxide retainers.

Non-hypercapnic CSA is due to increased sensitivity of the chemoreceptors leading to ventilatory changes, even to trivial changes in PCO_2. Some of the conditions associated with non-hypercapnic CSA include CSR in systolic congestive heart failure (CHF), sleep transition states, periodic breathing at high altitude and the initiation of CPAP therapy.

DIAGNOSIS

Clinical Assessment of Sleep-Related Breathing Disorders

History

This helps to identify the signs and symptoms of SRBD as well as to ascertain the differential diagnosis and to request for appropriate tests for diagnosis. The patient's routine sleep-wake schedule can also be ascertained.

Sleep schedule

The patient's sleep patterns, onset of sleep, awakening including weekdays and weekends is elicited. This data is compared with that of polysomnography.

Sleep problems

There are number of sleep disorders with overlapping symptoms. A thorough sleep history is essential and questions detailing the signs and symptoms of sleep disorders must be asked.

Family and medical history

Risk factors for SRBD include male gender, obesity, middle age or older individuals, crowded airways and anatomic abnormalities like retrognathia or micrognathia, large tongue and low set palate.

Medications

Details of medications being used by the patient, especially stimulants, wake promoting substances, sedatives-hypnotics and other sleep promoting substances must be elicited.

Questionnaires

Sleep questionnaire

Validated sleep questionnaires include the Sleep Disorder's Questionnaire and the Pittsburgh Sleep Questionnaire.

Sleepiness questionnaire

The most widely used questionnaire in clinical practice is the Epworth Sleepiness Scale. Others include the Karolinsky Questionnaire, the Stanford Sleepiness Scale, the Profile of Mood States, the Pictorial Sleepiness Questionnaire, the Berlin Questionnaire, and a number of other visual analogue scales.

Depression questionnaire

Commonly used screening tools include Zung Depression Inventory and the Beck Depression Inventory.

Laboratory Assessment

The current standard technique of diagnosing SRBD is attended laboratory polysomnography (PSG).

Sleep is characterised by three states: wakefulness, non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Non-rapid eye movement sleep consists of 1, 2, 3, and 4 while REM sleep consists of a single stage that is divided into phasic REM and tonic REM sleep. These sleep stages are defined by recordings taken by electroencephalographic (EEG) activity recorded from central and occipital derivations, electrooculographic (EOG) activity from left and right eye and from submental electromyographic (EMG) recordings. Sleep stages are recorded in 30 second epochs. The total length of recording is called the total recording time (TRT). The addition of all the epochs scored in one of the five sleep stages, after sleep onset, is called the total sleep time.

Advancements in PSG recordings have made it possible to collect data other than EEG, EOG, EMG, electrocardiogram (ECG), oxygen saturation and snoring intensity like Oesophageal pH, accessory EMG and nasal pressure. These data are useful in diagnosing conditions like nocturnal acid reflux . Sleep apnoea is graded as mild (AHI 5 to 15), moderate (AHI 15 to 30) and severe (AHI >30), as per the American Academy of Sleep Medicine. After a diagnosis of sleep apnoea is established, a continuous positive airway presure (CPAP) titration is done and the 'split-sleep ' study does away with the conventional two-night sleep study. Infant and pediatric sleep studies are possible with the help of specialised personnel using paediatric specific equipment.

TREATMENT

Treatment options for OSA are outlined in **Table 2**.

Table 2: Treatment Options for Obstructive Sleep Apnoea Syndrome

General measures
Change of position during sleep
Avoidance of alcohol and sedatives
Oxygen therapy
Sleep hygiene
Specific measures
Oral appliances
Continuous positive airway pressure
Bi-level positive airway pressure
Auto-adjusting positive airway pressure
Surgical treatment
Nasal Reconstruction
Uvulectomy
Pillar procedure
Tonsillectomy and/or adenoidectomy
Uvulopalatopharyngoplasty
Laser-assisted pharyngoplasty
Linguloplasty
Genioglossus advancement
Thyrohyoid suspension
Maxillomandibular advancement
Tongue base surgery
Radiofrequency ablation
Tracheotomy

Oral Appliances

Oral appliances are now being considered as first-line treatment for patients with mild to moderate OSA, though previous literature was contrary to this. Oral appliances have been found to be as useful as CPAP in improving subjective sleepiness. A retrospective study done in patients with severe OSA, reporting to a single dental sleep clinic, showed reduction of AHI by 50%. A repeated PSG with the oral appliances in place is essential, in order to make appropriate adjustments.

Continuous Positive Airway Pressure Treatment

Positive airway pressure (PAP) devices act like a pneumatic pump supplying positive pressure to the upper airways, thereby preventing collapse and occlusion during sleep. CPAP has been demonstrated to reduce the AHI and improve subjective and objective sleepiness. Despite its demonstrated efficacy, the adherence to therapy is suboptimal. An estimated 15% to 30% of the patients do not accept CPAP treatment and upto 25% of the patients discontinue the treatment within the first year. Average adherence to PAP has been estimated at 65%. Other PAP delivery modes which may provide greater comfort and better adherence are the auto-adjusting PAP (APAP), Bi-level PAP (Bi-PAP) and flexible PAP (C-Flex). The APAP devices have the ability to simultaneously detect and prevent upper airway obstruction using the lowest possible pressure during sleep. Bi-PAP devices deliver two independently adjusted levels of pressure: high pressure during inhalation and a low pressure during exhalation. C-Flex devices lower the pressure level at the beginning of exhalation, returning to set pressure before exhalation ends. It is thought that the flexible amount of pressure relief causes an increase in comfort to the patient, thereby resulting in better therapeutic adherence. There are ongoing studies on the use of cognitive behavioural therapy and theory based music intervention as means of improving adherence to CPAP therapy.

Surgical Treatment

Once surgical treatment is indicated, conservative procedures must be tried first and only after that, comes the aggressive procedures and second-line treatments. Since the introduction of uvulo-palatopharyngoplasty (UPPP) in 1981, it is the most common procedure for treating OSA.

CLINICAL OUTCOMES AND MORTALITY IN OSA

The various clinical outcomes in patients with OSA are listed in **Table 3**. The risk of death among patients with untreated severe OSA is about three times that of the general population or of those patients with mild OSA. The increased risk of mortality was seen in younger patients, prompting the suggestion that diagnosis and treatment be done early.

Table 3: Clinical Outcomes in Obstructive Sleep Apnoea

Death
Cardiovascular
Non-fatal myocardial infarction
Non-fatal stroke
Heart failure
Arrhythmias
Pulmonary hypertension
Systemic hypertension
Traffic accidents
Daytime sleepiness

23.16 Pulmonary Embolism and Deep Vein Thrombosis

Jamshed D Sunavala, Shruti M Tandan

DEEP VENOUS THROMBOSIS

Deep venous thrombosis is commoner than generally perceived; one of four patients admitted for a general medical condition to a hospital develops deep venous thrombosis. Incidence in Indian population varies between 8% and 28% in hospitalised patients; 50% and 60% in patients undergoing hip/knee surgeries.

Deep venous thrombosis (DVT) is most common in the lower limbs, particularly in the venous sinuses of the soleus muscle in the calf and in the femoral and iliac veins. It is much less frequent in the upper limbs, but the axillary vein may be involved as a complication of trauma, long venous-infusion catheters, neoplasm or radiotherapy. Virchow's triad attributes venous thrombosis to three factors: relative venous stasis, endothelial injury and increased coagulability (**Table 1**).

Table 1: Predisposing Factors for Deep Vein Thrombosis

Venous stasis
Immobility (bed rest, surgery, limb paralysis), low cardiac output
Varicose veins
Venous injury
Trauma, intravenous cannulation
Increased coagulability
Malignant disease, drugs (e.g. oestrogens, oral contraceptives), dehydration, polycythaemia, nephrotic syndrome, ulcerative colitis, lupus anticoagulant
Inherited coagulation defects
Antithrombin-III, protein C, protein S deficiency, factor V Leiden mutation, anticardiolipin antibodies
Increasing age

Pathology

Normal endothelium is non-thrombogenic. However, change or injury to the endothelium can trigger the activation of platelets finally leading to adhesion and aggregation of platelets. Endothelium can also be activated to release activators of certain coagulation factors (factor X) due to injury or as result of hypoxia following stagnation of blood due to venous stasis. Activated clotting factors lead to fibrin formation. Initially, the thrombus consists mainly of dense layers of platelets and fibrin. Later, the jelly-like mass of fibrin and red cells may become detached to form an embolus. After a few days, inflammatory changes occur in the wall of the vein, the thrombus may undergo lysis and organisation.

Diagnosis

Most patients have no physical signs. DVT and pulmonary thromboembolism (PTE) may occur in healthy people with no predisposing cause. In a patient suspected to have DVT, a detailed history is elicited and careful inspection of the extremity is performed. One would look for redness, warmth, tenderness on calf compression (Moses' sign), measure the leg circumference and try to elicit Homan's sign (calf pain on dorsiflexion of foot with the knee bent). However, very often the patient is completely asymptomatic. Recent evidence suggests that 1% of all asymptomatic calf DVT patients that go home will die of PTE. A high level of suspicion is, thus, necessary to detect patients with increased risk of DVT as shown in Well's DVT scoring system (**Table 2**).

Table 2: Well's DVT Scoring System: Score <0—Low Risk, 1 to 2—Moderate Risk, >3—High Risk

History	Score
Paralysis, paresis or plaster immobilsation of the legs	+1
Major surgery in past 4 weeks, or being bedridden for 3 or more days, or travel lasting longer than 4 hours in the previous 6 weeks	+1
Cancer treatment in previous 6 weeks, or on palliative treatment	+1
Clinical findings	
Entire leg swollen	+1
Calf swollen; in the symptomatic leg, the circumference is 3 cm more than the other leg, measured 10 cm below the tibial tuberosity	+1
Tenderness along deep veins	+1
Pitting oedema (worse in the symptomatic leg)	+1
Collateral superficial veins (non-varicose)	+1
Other alternate diagnosis	
For example: musculoskeletal injuries, haematoma, chronic oedema, superficial phlebitis in varicose veins of the leg, cellulitis of the leg, arthritis of the leg, Baker's cyst	–2

Investigations

Duplex ultrasound

The technique called duplex ultrasound, which includes venous compression ultrasound (CUS) and the Doppler ultrasound, has a high sensitivity (90% to 100%) and specificity (80% to 100%) for diagnosis of DVT in the thigh. It is less sensitive (75%) for detection of DVT in the calf veins.

In CUS, a vein with an indwelling thrombus is not obliterated by external compression; thus, failure to obliterate the femoral vein by external compression is an indirect evidence of femoral vein thrombosis. This method uses a two-dimensional B-mode ultrasound. Doppler ultrasound, on the other hand, uses the Doppler shift method to detect the velocity of flow in an underlying vessel. This combined duplex approach is more accurate than either method alone.

Impedance plethysmography

Impedance plethysmography (IPG) is a reliable method for detecting thrombi in the deep veins of the thigh (sensitivity and specificity ~ 90%). However, IPG can miss thrombi in the calf veins where its sensitivity is less than 70%, as calf thrombi produce relatively little venous obstruction.

Contrast venography

Though it remains the 'gold standard' for confirmation of DVT, contrast venography is an invasive test and involves administration of contrast medium. It is contraindicated in patients with renal insufficiency and is not accurate in patients with recurrent DVT because of the difficulty in visualising an intraluminal defect in veins that have been thrombosed previously. It is seldom used presently.

Treatment

Therapeutic anticoagulation is the mainstay of management of DVT (**Table 3**), which also includes treatment with analgesics for local pain, elastic bandaging and elevation of the leg, prevention of further clotting, and prophylaxis against recurrent pulmonary emboli. The purpose of the bandage is to compress superficial veins and so promote increased blood flow through the deep veins.

Table 3: Therapeutic Anticoagulation in VTE

Initiation
Admit for close observation. Check baseline coagulation profile
Initiate intravenous UFH 80 µ/kg as bolus followed by 18 µ/kg/hr
Monitor ACT/aPTT 6 hourly, titrate infusion to maintain 1.5 to 2 times normal value
Initiate VKA on day 1 of therapy
Check INR on day 3
Heparin (UFH/LMWH) may be stopped after a minimum of 5 days and once INR ≥2 for >24 hours
LMWH in a dose of 1 mL/kg SC q12h may be an alternative, but UFH is preferred in renal failure
Maintenance
Therapeutic anticoagulation is mandatory for 3 to 6 months in all patients with first episode of VTE with a reversible risk factor (e.g. pregnancy/trauma)
Prolonged, i.e. lifelong anticoagulation is required in patients with recurrent (>1) episode, unprovoked first episode (no identifiable risk factor, low risk of bleeding), patients with malignancy

VTE = Venous thromboembolism; UFH = Unfractionated heparin; LMWH = Low molecular weight heparin; VKA = Vitamin K antagonist.

Consequences of DVT may vary from complete resolution of the clot to death due to pulmonary embolism. Morbidity associated with DVT includes post-thrombotic syndrome that includes chronic venous hypertension causing limb pain, ulcers, hyperpigmentation, swelling, dermatitis, venous gangrene, and lipodermatosclerosis. Elastic compression stockings protect against post-thrombotic syndrome by decreasing the incidence to half.

VTE is being recognised as a relapsing disorder in a number of patients, particularly those with thrombophilia, malignancy and in patients with more than one episode of DVT. These patients require long-term anticoagulation. Persistently elevated D-dimer levels (after stopping anticoagulation) or persistent residual venous thrombosis on Doppler help to identify this subset of patients following the first episode of DVT.

Prophylaxis

Almost all critically ill patients and some post-operative patients have significant risk factors for venous thromboembolism. A reasonable strategy is to extend anticoagulation prophylaxis to all immobilised critically ill patients and also to moderately high-risk general surgical patients, unless there are contraindications to such therapy. Prophylaxis for DVT includes pharmacological and/or mechanical prophylaxis (**Table 4**). Certain high risk groups (poly trauma/bariatric surgery) require a combination of both methods.

Table 4: Deep Venousthrombosis Prophylaxis

Methods of prophylaxis	
Mechanical	Graded compression stockings Sequential compression device Venous foot pump
Pharmacological	Low-dose UFH LMWH fixed-dose irrespective of body weight (e.g. Enoxaparin 40 mg SC q24h) Fondaparinux 2.5 mL SC q24h VKA

Patient groups	**Recommendation**
Low risk: <10% Laparoscopic/urologic/gynaecologic surgeries for benign conditions/ minor surgeries lasting <30 min requiring LA/spinal anaesthesia	Early ambulation
Moderate: 10% to 40% Surgery >30 min requiring GA/ medically ill patients	Risk of bleeding: mechanical No risk: UFH/ LMWH
High: 40% to 80% Hip/knee/spinal cord surgeries/ oncosurgeries/bariatric surgeries/ critically ill patients/polytrauma/SCI	Risk of bleeding: mechanical No risk: UFH/ LMWH

UFH = Unfractionated heparin; LMWH = Low molecular weight heparin; VKA = Vitamin K antagonist; LA = Local anaesthesia; GA = General anaesthesia; SCI = Spinal cord injury.

PULMONARY THOMBOEMBOLISM

Definition

Pulmonary thromboembolism (PTE) is defined as a condition where there is significant obstruction of a part or whole of the pulmonary arterial tree by a thrombus, migrating from a site outside the lung. PTE is not a disease per se, but is a complication of DVT in most cases. The primary source of PTE is from thrombi arising in the deep veins of the lower extremities (90%). The term venous thromboembolism (VTE) is commonly used to include both DVT and PTE as a continuum of one aetiopathological process.

Epidemiology

PTE is being more frequently recognised due to increasing awareness and advances in diagnostic techniques. The incidence of PTE in India is assumed to be less than in the Western countries. One reason for this may be the lack of diagnostic facilities at most centres in India. In USA, it accounts for about 10% of in-hospital mortality; 10% of these occur in the first hour, timely treatment reduces mortality from 30% to less than 10%.

Aetiology

PTE is a complication of DVT and most commonly results from the detachment of a vascular thrombus from the leg (70% to 80%) or pelvis (10% to 15%). Thrombi which are confined to the veins below the knee appear to pose lower risks than those arising above the knee.

Pathophysiology

Acute alteration in haemodynamics and respiratory physiology occur when massive PTE occludes pulmonary arteries. These effects occur due to physical obstruction and serotonin release due to pulmonary vasoconstriction. On the other hand, pulmonary infarction is less common as the lungs receive dual blood supply from the bronchial circulation. The pathophysiological consequences of PTE are shown in Table 5.

Table 5: Haemodynamic Presentation of Pulmonary Thromboembolism

Massive	Moderate to severe	Mild to moderate
>50% in PV bed	>50% ↓ in PV bed	<50% ↓ in PV bed
↑↑ PVR	↑ PVR	PVR – normal
↑↑ RV after-load	↑ RV after-load	Normal RV after-load
RV failure	RV dysfunction	No RV dysfunction
↓ CO, shock	No shock	No shock

PV bed = Pulmonary vascular bed; PVR = Pulmonary vascular resistance; RV = Right ventricular; CO = Cardiac output.

Clinical Evaluation

The clinical manifestations of PTE are variable and often non-specific. While sudden and unexpected death may result during convalescence after an operation or a prolonged medical illness, PTE can, at times, be totally symptomless. Patients with massive PTE (Figure 1) present with substernal pain that may be indistinguishable from the pain of coronary thrombosis and/or dyspnoea. These patients may be anxious, restless, confused and cyanosed. Signs of shock may supervene. Tachycardia and tachypnoea and a gallop rhythm are frequently evident. Occurrence of other findings such as an accentuated pulmonary component of the second heart sound and rise in jugular venous pressure will depend on the degree of pulmonary hypertension produced. The chest is usually clear. Rhonchi may be heard as a result of secondary bronchoconstriction.

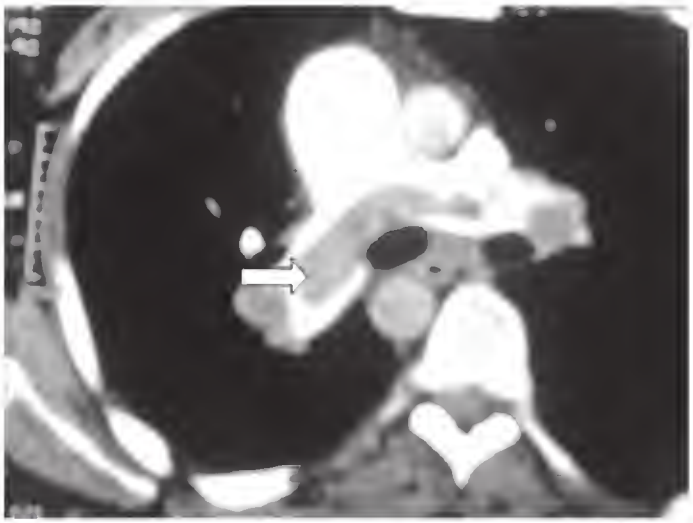

Figure 1: CT pulmonary angiography showing saddle thrombus extending from the main pulmonary artery into right and left branches (arrow).

Many patients with smaller or often recurrent emboli present in a more insidious manner. Dyspnoea may be the only symptom; unexplained dyspnoea should always raise the suspicion of pulmonary embolism. Pleuritic chest pain and haemoptysis indicate pulmonary infarction and their onset may be delayed for a day or more after the initial presentation. A pleural rub may be heard over the affected area. A pleural effusion, small or large, may develop and persist for weeks. Fever is usually present and is persistent when the embolus is of an infective nature. A mild icteric tinge may be evident.

Investigations

Radiographic assessment

The chest radiograph, even in patients with life-threatening PTE, may appear normal. The most frequent radiographic abnormalities in PTE are atelectasis or a pulmonary parenchymal abnormality. The Hampton hump is a classic finding caused by a pleural-based abnormality from pulmonary infarction but its absence cannot be used to exclude PTE. The overall specificity and sensitivity of a chest radiograph, as a diagnostic tool, is very low. Therefore, the major role of the chest radiograph is to exclude other possibilities that may mimic PTE such as pneumonia, pneumothorax and to provide information that could help in the interpretation of radionuclide scans.

Electrocardiogram

The electrocardiogram (ECG) is normal in 70% to 80% of patients with PTE. Sinus tachycardia is the most common ECG abnormality especially when the emboli are small. Right axis deviation and clockwise rotation of the heart may be present. The deep S wave in lead I, a prominent Q wave and inverted T wave in lead III, commonly referred to as the S_1, Q_3, T_3 mimicking inferior myocardial infarction, are highly suggestive of PTE. Depression of the ST segment may occur in lead I and lead II. T waves in leads V_1 to V_4 may be inverted, while the P waves are prominent in lead II and VI (Figure 2).

In an appropriate clinical setting, transient development of incomplete or complete right bundle branch block (RBBB) is strong supportive evidence of PTE. Recurrent episodes of arrhythmias, e.g. sinus tachycardia, atrial flutter or atrial fibrillation may also occur. ECG changes are often transitory, lasting from a few hours to a few days or a week. Thus, serial ECGs are of great diagnostic help. It must, however, be kept in mind that a normal ECG does not exclude the diagnosis of PTE. ECG is also useful for excluding acute myocardial infarction.

Arterial blood gas abnormalities

Hypoxia and hypocapnia is the main arterial blood gas abnormality. However, massive PTE may be accompanied by significant increase in dead space reflecting as hypercapnia and respiratory acidosis, with low end-tidal CO_2.

In most instances, the disturbed blood gas balance will rapidly normalise. This is probably due to an equalising of lung units with low and high V/Q ratios. This happens as a consequence of physiological reflexes causing both hypoxia-induced vasoconstriction to ventilated lung units and bronchoconstriction following hypocapnia to underperfused lung units. However, if there is already an underlying lung disease, such as COPD, these reflexes may fail and the overwhelming V: Q abnormality may persist.

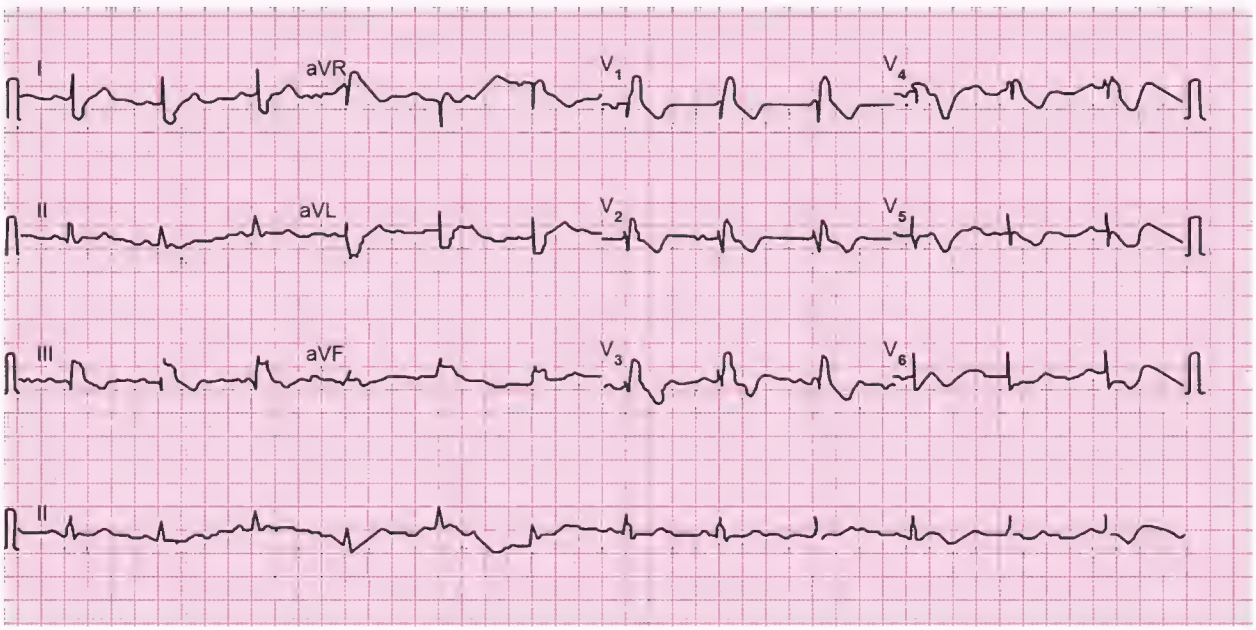

Figure 2: ECG showing $S_1Q_3T_3$ pattern and RBBB in a patient with pulmonary thromboembolism.

Echocardiogram

Two-dimentional-echocardiography (2D-echo) is particularly useful as it reveals abnormalities of right ventricular (RV) dysfunction manifest by RV dilation, hypokinesia, septal flattening or tricuspid regurgitation. The presence of RV dysfunction and pulmonary hypertension on 2D-echo in the right clinical setting strongly suggests a massive PTE (**Figure 3**).

Plasma D-dimer

Plasma D-dimers are fibrin derivatives produced by plasmin-mediated clot degradation. An abnormally elevated level of D-dimer by ELISA method has a high sensitivity (>95%) but poor specificity for identifying patients with PTE. This is because D-dimer may be elevated in a number of other conditions that are often commonly associated with VTE, e.g. pregnancy, sepsis,

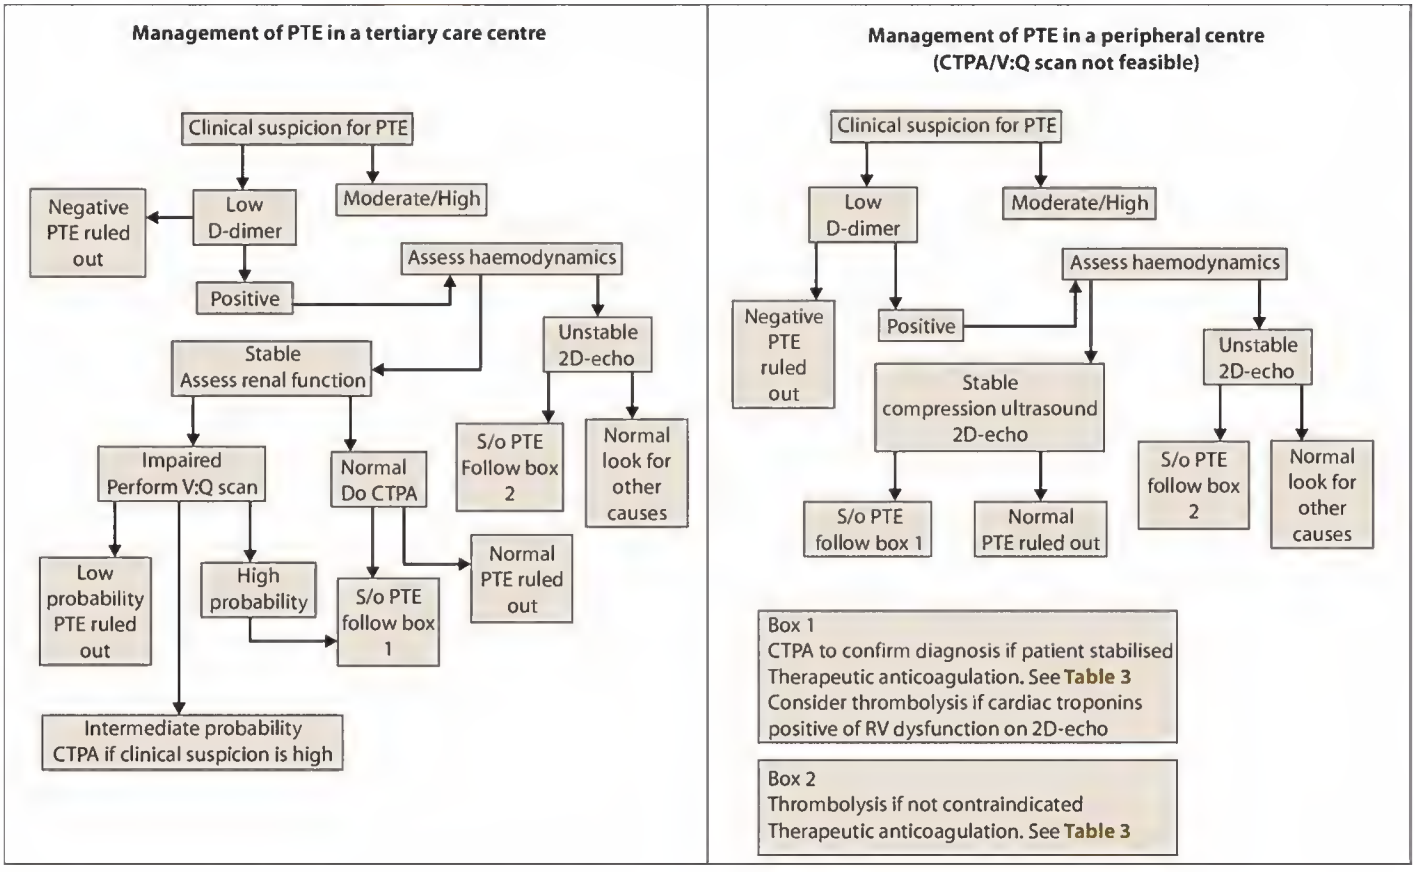

Figure 3: Management of Pulmonary Thromboembolism (PTE).

trauma, recent surgery. Albeit the test has a high negative predictive value, i.e. a normal value can virtually exclude the possibility of venous thromboembolism especially in patients with low clinical suspicion.

Ventilation-perfusion scan

In lung perfusion scan, a suspension of particles of macro-aggregated human albumin labelled with technetium99m is injected intravenously. The area of the lung which is under-perfused shows up a 'cold spot' or 'avascular' area in the scan. A normal perfusion scan virtually excludes the diagnosis of PTE.

In a ventilation scan, radioactive xenon-133 is inhaled and exhaled by the patient, while the gamma camera records its distribution throughout the alveolar gas exchange units. The test is based on the assumption that ventilation is preserved in areas of reduced perfusion due to pulmonary embolism and is abnormal when perfusion defects are due to pulmonary lung disease. V/Q scanning is useful in patients with moderate-to-high clinical suspicion where contrast dye is to be avoided. (**Figure 3** for algorithm for diagnostic strategy).

CT pulmonary angiography

CT pulmonary angiography (CTPA) is a minimally invasive investigation, widely available in most major hospitals, and offers the advantage of direct visualisation of pulmonary emboli within the pulmonary arteries. It also provides information about parenchymal abnormalities that may help in establishing an alternative diagnosis. CTPA is more accurate in detecting central or lobar PTE and less sensitive in detecting subsegmental PTE. Hence, CTPA cannot rule out the possibility of subsegmental PTE and this is the main disadvantage from conventional pulmonary angiography. However, isolated subsegmental PTE is uncommon and in presence of a negative CTPA one can safely withhold anticoagulation and on the other hand, a CTPA showing a PTE (**Figure 1**) may be treated without further tests.

Conventional pulmonary angiography

Formerly the 'gold standard' for diagnosis of PTE, the use of pulmonary angiography has declined with the advent of modern CTPA. It is more often used as an imaging modality as a part of local thrombectomy.

Cardiac markers

Cardiac troponins often elevated in massive PTE are indicative of significant right ventricular dysfunction, thus, helpful in prognostication rather than diagnosis. BNP elevation may indicate RV strain and stretching of RV muscle, which may suggest a serious prognosis. However, it may be elevated in other coexisting conditions like CHF and hence is of little value.

Treatment of Massive PTE

Massive PTE is a life-threatening medical emergency which is often undiscovered until autopsy. Diagnosis heavily relies on clinical suspicion together with CTPA or V/Q scanning. Unfortunately, most patients with massive PTE are clinically unstable and this may delay proper diagnostic evaluation and specific therapeutic intervention. However, the central aim initially is to counter the respiratory and haemodynamic consequences of the embolus till such time as reasonable diagnostic evaluation is possible (**Figure 3**). Echocardiography is an excellent bedside technique, which helps in recognising RV failure and haemodynamic instability, so that proper therapy is instituted in this selected group of patients. After initial supportive measures, most patients may be reasonably stable to be transported to CTPA for further evaluation.

Initial management in the presence of hypotension would include volume resuscitation. However, fluids should be administered cautiously particularly in the presence of marked increase in pulmonary vascular resistance and RV failure, where volume resuscitation may further compromise RV function resulting in more drastic reduction in the cardiac output. Among the vasoactive agents, norepinephrine and dobutamine have been reported to show haemodynamic improvement most consistently. If the patient remains haemodynamically stable, with or without supportive treatment, prompt anticoagulation with heparin should be started (**Table 3**). However, if in spite of initial resuscitation and all supportive measures, the cardiac output is not adequately restored and the patient remains haemo-dynamically unstable, one must consider therapeutic options aimed directly at reducing the embolic burden like intravenous or catheter-directed thrombolytic therapy (can be administered within 14 days of diagnosis of PTE) or surgical embolectomy. Further, thrombolytic therapy may be considered in some cases of PTE with RV dysfunction or elevated cardiac troponin levels. When there are contraindications to its use (**Table 6**) or if the hypotension is refractory despite thrombolytic therapy, embolectomy should be considered. Certain other scenarios such as trapped embolus within the right atrium or right ventricle may necessitate surgery. Approved dosage regimes for thrombolytic therapy in acute PTE are shown in **Table 7**.

Table 6: Contraindications to Thrombolytic Therapy

Absolute	
	Active internal bleeding
	Bleeding diathesis
	Recent GI bleeding/proven peptic ulcer (in last 3 months)
	Previous haemorrhagic stroke/CVA in last 6 months/intracranial tumour
	Recent (<2 months) head injury/any trauma/major surgery
	Severe uncontrolled hypertension (diastolic BP >110 mm Hg)
	Allergy to earlier treatment with streptokinase (use alternate agent)
Relative	
	Pregnancy, post-partum state
	Chronic liver disease
	Cardiopulmonary resuscitation
	Haemorrhagic retinopathy

Table 7: Thrombolytic Treatment of Pulmonary Thromboembolism

Streptokinase	
	250,000 U IV (as loading dose) over 30 minutes followed by 100,000 U/hour for 24 hours
Urokinase	
	4,400 U/kg body weight IV (as loading dose over 10 minutes) followed by 4400 U/kg/hour for 24 hours
Tissue plasminogen activator	
	100 mg IV over 2 hours

Placement of inferior vena caval (IVC) filters may prevent additional, potentially fatal emboli in a selected group of patients with massive emboli. The main indications for using

IVC filters are recurrent PTE despite anticoagulation, patients who develop bleeding on anticoagulation, large free-floating thrombus in the ileofemoral veins, immediately following surgical catheter embolectomy and in high-risk patients where anticoagulation and thrombolytic therapy is contraindicated. More recently, temporary (retrievable) filters have been placed in patients with short-term risk of bleeding. Interestingly, IVC filters are a potential nidus for thrombus formation and often mandate a low level of anticoagulation.

Chronic thromboembolic pulmonary hypertension (CTPH) represents partly a failure of initial treatment of PTE and develops in less than 4% of patients following the first episode, and the incidence increases following recurrent VTE.

In patients with recurring episodes of PTE and no known predisposing factors or in patients with a strong family history of PTE, it is mandatory to do an assay of protein C, protein S, homocysteine and AT-III and look for factor V Leiden mutations. In cases of AT-III deficiency or homozygous factor V Leiden, long-term or even lifelong anticoagulation is recommended. However, all patients should receive heparin prophylaxis during surgery or trauma.

Pregnancy

Physiological changes in pregnancy and post-partum period may predispose to development of DVT in the legs and pelvic veins. VTE was previously observed to be more common in the post-partum period possibly related to earlier practices of prolonged bed rest after delivery or use of oestrogen to suppress lactation. Now, it is equally common to document DVT in all trimesters of pregnancy. Important risk factors include increased parity, obesity, prolonged immobility, operative or difficult instrumental delivery and previous history of VTE. Multiple risk factors are often present during pregnancy. Interestingly, there is a striking propensity for left leg involvement (nearly 80%) when DVT occurs in pregnancy probably due to the tortuous course of left leg venous drainage through the pelvis. Mortality has been reported at 15% in undiagnosed patients and in Western countries, PTE is an important cause of maternal mortality.

Clinical diagnosis of VTE is notoriously unreliable because the physiological changes in pregnancy can complicate the interpretation of the usual signs and symptoms of VTE; elevated D-dimer levels are common in uncomplicated pregnancy. Ultrasound and Doppler studies of the leg veins are the investigations of choice. Diagnostic work-up for thrombophilia is not indicated in all cases of DVT in pregnancy except in selected cases with strong clinical suspicion of hypercoagulable state.

Main aims of management include restoration of venous patency to prevent post-phlebitic syndrome in the future and prevent PTE. Bed rest and elevation of the affected leg promotes venous return and decreases oedema. However, as soon as symptoms permit, the patient should be ambulated as there is no evidence to show that prolonged bed rest prevents detachment of the embolus. Coumarin is not used in pregnant patients as it produces haemorrhagic complications in the foetus and carries the risk of warfarin embryopathy (manifests as skeletal or CNS defects), hence intravenous and subcutaneous heparin or LMWH is the treatment of choice.

Management of Bleeding Caused by Anticoagulant Treatment

In an emergency for rapid reversal of anticoagulation following warfarin treatment, both vitamin K (10 mg IV slowly) and fresh frozen plasma (FFP) must be given to correct the international normalised ratio (INR). Recombinant factor VIIa (rVIIa) can also be used in an emergency as it is effective for a prompt and complete reversal. Protamine is used for immediate reversal of standard heparin (1 mg of protamine for every 100 units of standard heparin if the last dose of heparin was given within 30 minutes and 0.5 to 0.75 mg/100 units of heparin if it was 30 to 60 minutes since the last dose) and LMWH (1 mg of protamine for every 1 mg of LMWH). Protamine does not fully reverse LMWH but can neutralise the antithrombotic effect. Because of the longer half-life of LMWH, a second dose of protamine may be required.

NON-THROMBOTIC PULMONARY EMBOLISM

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare complication of pregnancy wherein amniotic fluid and foetal cells enter the maternal pulmonary circulation and trigger an anaphylactic reaction or complement activation or both. This leads to pulmonary vasospasm and pulmonary hypertension causing hypoxia which damages myocardial and pulmonary capillaries, resulting in LVF and ARDS. This manifests as an acute catastrophe during labour and less commonly following an abortion or amnioinfusion. The patient may develop shock, respiratory distress, seizures, neurological manifestations and even cardiac arrest. Patients who survive this phase may progress to develop uterine atony and disseminated intravascular coagulation (DIC) leading to massive post-partum haemorrhage. Therapy is usually supportive. Steroids may have a role as anaphylaxis is postulated.

Air Embolism

Air embolism is often an iatrogenic complication that occurs frequently during neurosurgical procedures in the sitting position, less commonly during central line insertions, thoracocentesis, haemodialysis, radiographic procedures, penetrating chest injuries, etc. Air may enter the pulmonary circulation causing right ventricular outflow obstruction or alternately enter the cerebral circulation. Typically about 5 mL/kg of air is fatal but in the cerebral circulation, 2 to 3 mL and in the coronary circulation, 0.5 mL may be dangerous. Patients often present with a sudden cardiovascular collapse, dyspnoea or arrythmias. Movement of air through a patent foramen ovale may result in an arterial air embolism that may manifest as a myocardial infarction or stroke. Transoesophageal echo-cardiography/precordial duplex ultrasound or cranial Doppler are useful diagnostic modalities. Placing the patient in the left lateral Trendelenberg's position may preclude the air from moving into the right ventricle. High flow oxygen, attempts at air aspiration from an indwelling CVC, hyperbaric oxygen in the case of Caisson's disease are some of the suggested therapeutic modalities.

Fat Embolism

Fat embolism may occur due to the mechanical dislodgement of fat globules into veins which subsequently move into

cerebral circulation by arteriovenous shunts. These emboli cause microcirculatory defects, platelet aggregation and vasoactive amine release. An alternate theory is that trauma/sepsis causes the systemic release of free fatty acids or chylomicrons which coalesce and cause the above effects. Hence, fat embolism is common following trauma, orthopaedic procedures, parenteral lipid administration and in patients with multiple medical problems. Diagnosis of fat embolism may be defined based on presence of one major (respiratory distress, radiological signs, cerebral signs devoid of other aetiologies and petechial rash) and four minor criteria (pulse >110/m, fever >38.5°C, retinal changes of fat globules, elevated ESR, drop in haemoglobin or platelets, jaundice, renal dysfunction) plus fat microglobulinaemia. Treatment involves management of the orthopaedic condition, DVT prophylaxis, supportive care and steroids.

23.17 Diseases of Pleura, Mediastinum, Diaphragm and Chest Wall

Alladi Mohan

DISEASES OF THE PLEURA

The visceral pleura that lines the lungs, folds back itself at the hilum to form the parietal pleura which lines the inner thoracic wall, the mediastinum and the diaphragm. The cavity between the visceral and parietal pleura is termed the pleural space and it normally contains a very thin layer of fluid (0.13 mL/kg) which acts as a lubricant. Only the parietal pleura is pain sensitive as it contains sensory nerve fibres, supplied by the intercostal and phrenic nerves.

Pleurisy

Inflammation of the pleura results in pleurisy (or pleuritis). Pleurisy may start as dry pleurisy (**Table 1**), but may later on resolve or develop into wet pleurisy (pleural effusion). Patients with pleurisy present with a localised, sharp, stabbing pain on the affected side that worsens on inspiration, coughing, and sneezing (pleuritic pain). Physical examination may reveal reduced movements on the affected side. A pleural rub may be heard on auscultation.

Table 1: Common Causes of Dry Pleurisy

Epidemic myalgia (pleurodynia, Bornholm disease)
Extension of infection from the underlying lung (e.g. pneumonia)
Tuberculous pleurisy
Chest trauma
Serositis due to connective tissue diseases (e.g. rheumatoid arthritis, systemic lupus erythematosus)
Pulmonary infarction
Pleural malignancy (metastatic, primary)
Radiation injury
Uraemia

Pleurodynia (also called epidemic myalgia, Bornholm disease), caused by Coxsackie B virus infection, is a form of dry pleurisy which may occasionally be complicated with pleural effusion. It occurs in epidemics and commonly affects children and young adults. Patients present with fever, severe incapacitating pleuritic chest pain. On the affected side, movements of the thorax are reduced, the chest wall muscles are tender and a pleural friction rub may be heard. This condition should be differentiated from chest pain due to other causes such as, herpes zoster, intercostal myalgia, costochondritis, and rib trauma. Treatment is symptomatic and supportive and includes relief of pain by administration of analgesics.

Pleural Effusion and Empyema

Abnormal, excess accumulation of fluid in the pleural space is termed as pleural effusion. Presence of pus in the pleural space is termed empyema. Various causes of pleural effusion are listed in **Table 2A**.

Table 2A: Causes of Pleural Effusion

- **Transudate***
  - Congestive heart failure†
  - Constrictive pericarditis†
  - Restrictive cardiomyopathy†
  - Cirrhosis of liver (hepatic hydrothorax)†

    - Urinothorax
    - Post-radiation therapy

**Described in Table 2B; †May present with bilateral pleural effusion.*

Clinical Features

Patients with pleural effusion manifest symptoms due to inflammation of pleura, compromise of pulmonary mechanics or interference with gas exchange. Most present with pleuritic chest pain that corresponds to the affected area. Sometimes, pleuritic pain may be referred to the abdomen. Pleuritic pain in the lower chest with ipsilateral shoulder pain indicates diaphragmatic involvement. A dull aching pain may be evident in patients with malignant pleural effusion. Dry cough with minimal scanty sputum and dyspnoea are usually present. History of expectorating copious purulent sputum may suggest an empyema rupturing into a bronchus (bronchopleural fistula). Fever is a prominent symptom in empyema where it may be high grade, remittent and associated with chills and rigors, and in pleural effusions of infective or inflammatory aetiology.

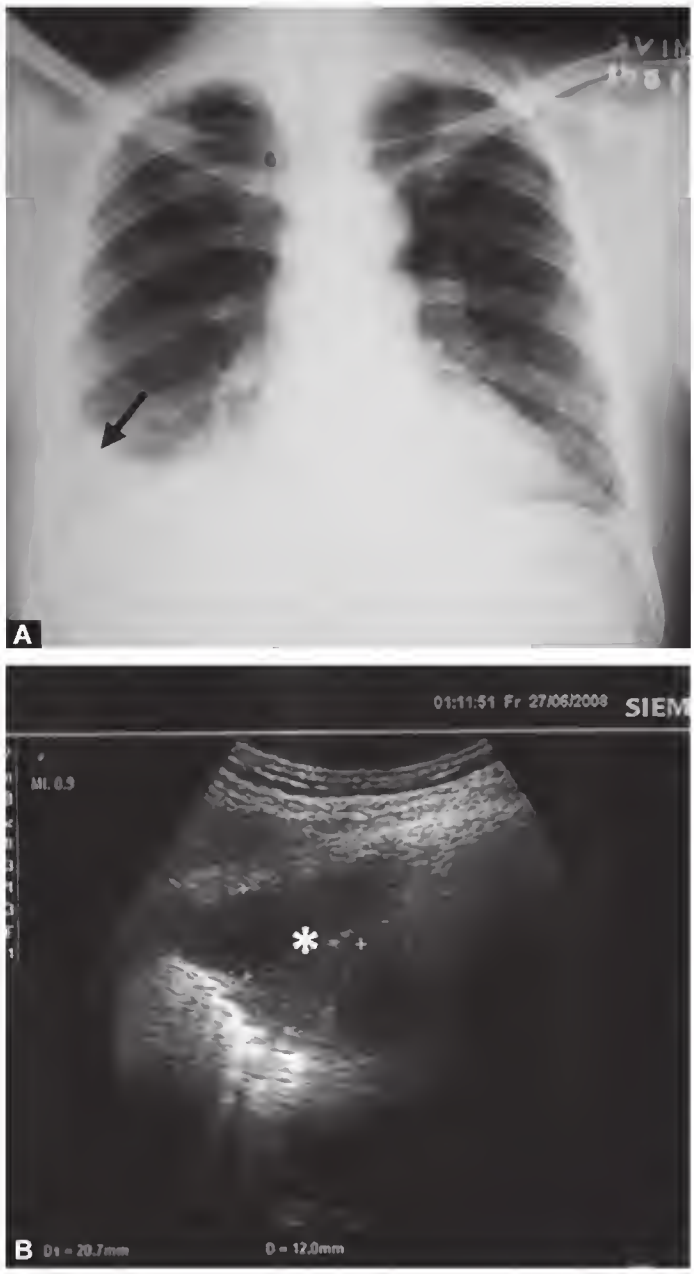
Physical examination reveals: reduced movements; impaired tactile and vocal fremitus; a stony-dull note on percussion. In pleural effusion, the highest point of the stony-dull note is evident in the axilla (*Ellis 'S' shaped curve phenomenon*). Breath sounds may be diminished or absent on the affected side. Aegophony may be heard at the upper level of the pleural effusion. Mediastinal shift to the opposite side may be evident in a large pleural effusion. Classical pleural friction rub, which is coarse, creaky and leathery in character, audible during the latter part of inspiration and the early part of expiration (*to-and-fro pattern*) may be present in the early stages of the disease; it may disappear when the pleural surfaces separate as a result of collection of excessive fluid, but may reappear in the stage of resolution. In empyema, intercostal fullness, bulging, redness and tenderness may be evident. With large pleural effusions, haemodynamic disturbances may be evident.

Diagnostic Evaluation

Chest radiograph

The chest radiograph findings of a pleural effusion range from blunting of costophrenic angle (small effusion) (**Figures 1A and B**) to dense opacification of the entire hemithorax with mediastinal shift to the opposite side (large effusion) (**Figures 2A to E**). Elevation of hemidiaphragm is seen in sub-pulmonic effusion. Encysted or interlobar effusions are better appreciated in the lateral view. Lateral decubitus chest radiograph obtained with the patient lying on the affected side can help in identifying small effusions. Pleural plaques (asbestosis) and pleural calcification (**Figure 3**) may also be present.

Ultrasonography



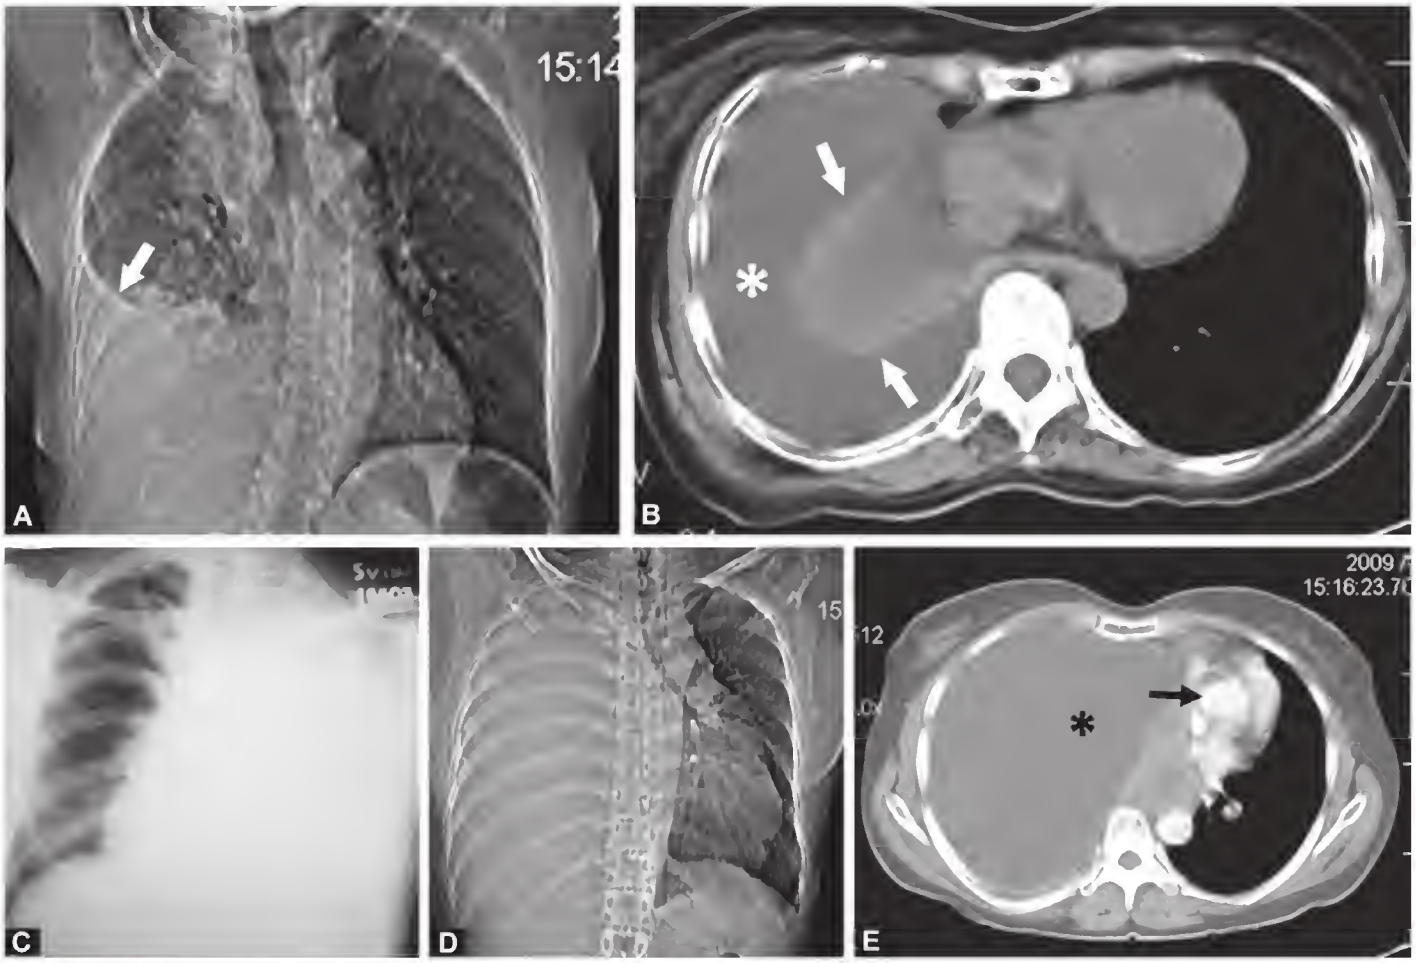
Ultrasonography of the chest is useful for detecting small pleural effusions (**Figure 1**), identifying multiloculated effusions and in localising the site for a diagnostic thoracocentesis.

Computed tomography

Computed tomography (CT) of the chest is useful for delineating loculated pleural effusion or empyema (**Figures 4A and B**), detecting mediastinal or hilar lymphadenopathy or lung lesions, such as tumours.

Thoracoscopy

Video-assisted thoracoscopic surgery (VATS) is a helpful procedure for obtaining tissue and fluid for ascertaining the aetiological diagnosis.



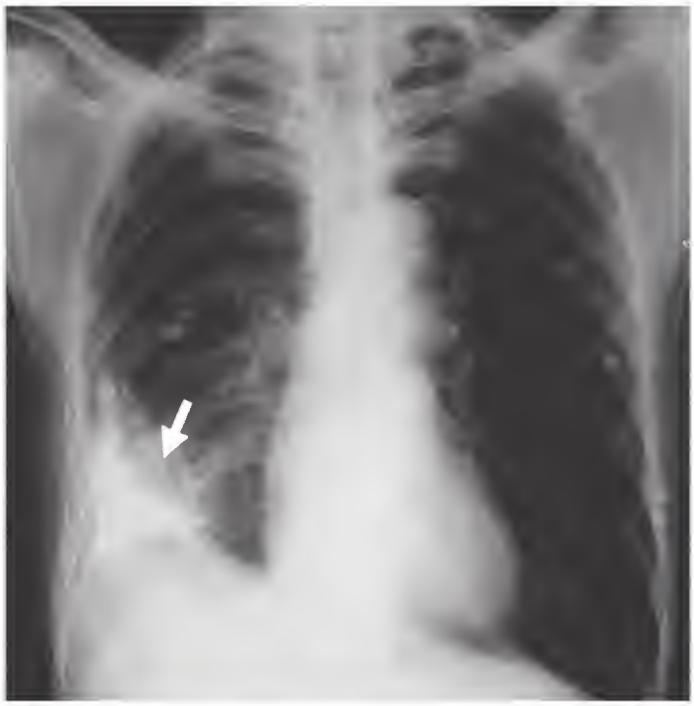
Figures 1A and B: (A) Postero-anterior view of chest radiograph (arrow), and (B) Ultrasonography of chest showing a small right-sided pleural effusion (asterisk). Ultrasonography helps in identifying small pleural effusions, facilitates quantification of the pleural fluid volume and also helps in the detection of loculation and septation.

Diagnostic thoracocentesis

Diagnostic thoracocentesis helps in categorising the pleural fluid as transudate or an exudate (**Table 2B**). A transudative pleural effusion occurs due to systemic factors, whereas an exudative pleural effusion occurs due to alteration in the local factors which influence the formation and absorption of pleural fluid. In acute infections, predominance of polymorphs may be present; in chronic infections, like tuberculosis (TB), lymphocytes predominate. In some cases, eosinophils predominate.

Transudative pleural effusions are usually clear, have low specific gravity, protein levels, lactate dehydrogenase (LDH) levels and very few cells. In transudative pleural effusion, pleural fluid glucose levels run parallel with blood glucose levels; pleural fluid glucose levels are reduced in exudative

Figures 2A to E: (A) Contrast-enhanced CT chest topogram(arrow) showing a moderate right-sided pleural effusion, (B) In the transverse CT (mediastinal window) image of the same patient, pleural effusion (asterisk) and the collapsed lung border (arrows) are also evident, (C) Chest radiograph (postero-anterior view) showing a massive left-sided pleural effusion and complete opacification of the left hemithorax with mediastinal shift to the right side, (D) Contrast-enhanced CT chest topogram of another patient showing a massive right-sided pleural effusion, (E) In the transverse CT (mediastinal window) image of the same patient, massive right-sided pleural effusion (asterisk) and mediastinal shift to the left side (arrow) can be seen.



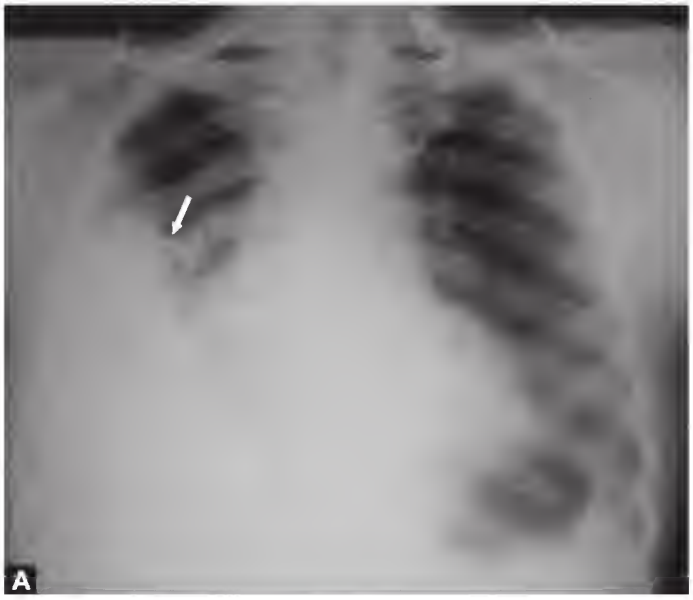


Figure 3: Chest radiograph (postero-anterior view) showing right-sided pleural calcification (arrow) that developed as a sequelae of a tuberculous pleural effusion.

pleural effusion. In rheumatoid pleural effusion, glucose levels may be very low (<60 mg/dL) and cholesterol levels may be high (especially in chronic effusions). In pleural effusions complicating pancreatitis, amylase levels are elevated. Adenosine deaminase (>36 IU/L), interferon-gamma (>112 pg/mL) levels are elevated in TB pleural effusion.

Table 2B: Criteria Used for Categorising a Pleural Effusion as an Exudate

Light's criteria	
	Pleural fluid protein: serum protein ratio >0.5
	Pleural fluid LDH: serum LDH ratio >0.6
	Pleural fluid LDH >two-third of the upper limit of normal serum LDH
Others	
	Pleural fluid protein >3 g/dL
	Pleural fluid LDH >200 IU/L
	Pleural fluid cholesterol >45 mg/dL
	Pleural fluid-to-serum cholesterol ratio >0.3
	Serum albumin-pleural fluid albumin gradient ≤1.2 g/dL
	Pleural fluid-to-serum bilirubin ratio >0.6

Aspiration of frank pus suggests empyema. A milky-white fluid suggests chylothorax or a chyliform (pseudochylous) effusion (**Table 3**). Haemorrhagic pleural effusions may suggest pleural malignancy. Pleural fluid seldom reveals acid-fast bacilli

Figures 4A and B: (A) Postero-anterior view of chest radiograph (arrow) showing a right-sided loculated pleural effusion, (B) Contrast-enhanced transverse CT (mediastinal window) image shows loculated pleural effusion on the right side (arrows).

on smear examination. Culture of pleural fluid for bacteria, mycobacteria or fungi can help in ascertaining the aetiological diagnosis. Cytopathological examination of pleural fluid confirms the presence of malignant pleural effusions. Molecular diagnostic methods such as polymerase chain reaction can be helpful in confirming the diagnosis in certain situations.

Pleural biopsy

Needle biopsy of the pleura using Abram's punch biopsy needle or Cope's needle, radiologically-guided Tru-cut needle biopsy can help in confirming histopathological diagnosis. Sometimes, VATS or open pleural biopsy may be required to confirm the diagnosis.

Management

In pleural effusion due to systemic causes like congestive heart failure, pulmonary embolism, treatment of the underlying cause facilitates the resolution of the effusion. In patients with synpneumonic effusion who continue to run fever, diagnostic thoracocentesis is indicated to rule out empyema.

In India, TB is the most common cause of pleurisy with effusion in young adults. Among middle-aged and elderly subjects who are smokers, malignant pleural effusion should be considered. Under the Revised National Tuberculosis Control Programme (RNTCP), patients with large or massive TB pleural effusion receive directly observed treatment, short course (DOTS), category I treatment and those with small to moderate TB pleural effusions, defined as pleural fluid volume less than 1,500 mL on ultrasonography of the chest, receive DOTS, category III treatment. A short course of prednisolone (0.5 mg/kg daily for 4 weeks) may be helpful in some cases to provide relief from toxaemic symptoms and to facilitate rapid absorption of fluid.

In malignant pleural effusion, treatment is aimed at the underlying malignancy. Rapidly reaccumulating pleural effusion requiring frequent thoracocentesis may require pleurodesis by injecting a sclerosant, such as, sterile talc or tetracycline. Intrapleural streptokinase administration may help if bacterial empyema is loculated; tube thoracostomy is often required in

Table 3: Differentiation of Chylothorax from Pseudochylothorax

Variable	Chylothorax	Pseudochylothorax*
Prevalence	Uncommon	Rare
Aetiology	Usually caused by thoracic duct transection (trauma, surgery); or obstruction (e.g. non-Hodgkin's lymphoma). Other causes: filariasis, lymphangioleiomyomatosis, congenital absence of thoracic duct, yellow nail syndrome	Often post-inflammatory; can be a feature of long-standing pleural effusions (e.g. tuberculosis, rheumatoid arthritis, empyema)
Onset	Acute to subacute	Insidious
Appearance	Milky; sometimes serous or haemorrhagic	Milky; satin-like sheen may be present
Pleural fluid analysis		
Evidence of thickened/calcified pleura	Usually not present	Usually present
Cell count	Lymphocyte rich	Neutrophils predominate
Total proteins	Exudative	Exudative; total protein level usually 4 to 7 g/dL
Lipid profile	Cholesterol 60 to 200 mg/dL; Triglycerides >110 mg/dL; Cholesterol/triglyceride ratio <1	Cholesterol >250 mg/dL; Triglyceride levels usually normal; may be elevated sometimes. Cholesterol/triglyceride ratio >1
Others		
Chylomicrons	Present	Absent
Lipid-laden macrophages	Absent	Present
Cholesterol crystals	Absent	Present (rhomboid shaped)
Addition of ethyl ether to milky fluid	Clears it by dissolving triglycerides	No change
Testing after consumption of butter containing radioiodine-labelled triglycerides; or containing lipidophilic dye (e.g. Sudan III)	Detection of dye/radioactivity	No detection of dye/radioactivity

** Also called cholesterol effusion, chyliform effusion*

such cases. In chronic empyema, Elossier flap procedure, decortication may be required.

Pneumothorax

Definition

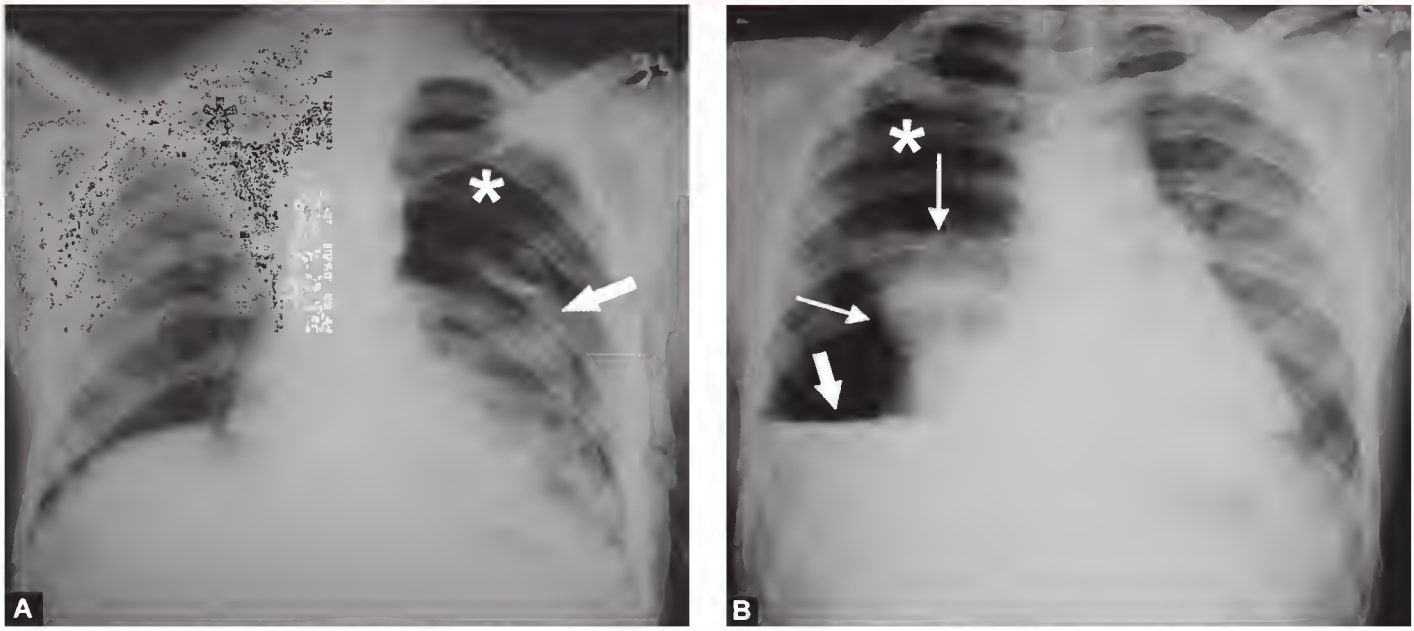
Presence of air in the pleural space results in pneumothorax. It may occur spontaneously or as a consequence of iatrogenic injury or trauma to the chest. Spontaneous pneumothorax may develop in otherwise healthy individuals (*primary*) or it can occur as a complication of underlying lung disease (*secondary*), e.g. due to the rupture of a subpleural emphysematous bulla, pleural bleb or as a complication of barotrauma due to mechanical ventilation.

Primary spontaneous pneumothorax

Various types of spontaneous pneumothorax are shown in **Table 4**.

Clinical Features

Primary spontaneous pneumothorax is commonly encountered in males, aged 15 to 30 years; tobacco smoking, tall stature and the presence of apical subpleural blebs are risk factors. Secondary pneumothorax, more common in older individuals affects patients with pre-existing lung diseases. Common presenting symptoms include sudden-onset chest pain on the affected side and breathlessness. In the closed type, breathlessness is mild. In the open type, breathlessness may be more severe and secondary infection of pleura is common. Tension pneumothorax is an acute medical emergency, the patient is severely dyspnoeic; cyanosis, marked tachycardia, profuse sweating may be present.



Physical signs vary according to the type and size of the pneumothorax. Mediastinum is shifted to the opposite side. On the affected side, intercostal fullness, diminished movements, hyper-resonant percussion note, reduced or absent breath sounds may be evident. In hydropneumothorax or pyopneumothorax, a horizontal 'fluid level' marks the interface between the liquid and the air. Other important physical signs include amphoric breath sounds (in bronchopleural fistula, tension pneumothorax) succussion splash (hydropneumothorax). Recurrent spontaneous pneumothorax can occur in patients with emphysematous bullae or lymphangioleiomyomatosis.

Investigations

Chest radiograph findings include mediastinal shift to the opposite side, presence of air in the pleural cavity as a translucent shadow along with the sharply defined edge of the collapsed lung (**Figures 5A and B**). Hydropneumothorax and underlying pulmonary disease may also be seen (**Figure 5B**).

Table 4: Types of Spontaneous Pneumothorax

Type	Pathophysiology	Salient Features
Closed	The communication between the lung and pleural space seals off as the lung deflates and does not reopen	The mean pleural pressure remains negative. Air in the pleural space gets reabsorbed spontaneously, the underlying lung re-expands over a few days or weeks. Infection is rare
Open	The communication between the lung and pleural space fails to seal. Air continues to transfer freely between the lung and pleural space. Usually develops following rupture of a tuberculosis cavity, an emphysematous bulla or lung abscess into the pleural space	The mean pleural pressure remains equal to atmospheric pressure; lung cannot expand. Bronchopleural fistula, spread of infection from the airways into the pleural space resulting in empyema are common
Valvular (tension)	The communication between the airway and the pleura acts as a one-way valve allowing air to enter the pleural space during inspiration but not to escape on expiration. This results in large amounts of air being trapped in the pleural space	The intrapleural pressure may become more than the atmospheric pressure. This may cause mediastinal shift towards the opposite side, compression of the opposite normal lung, impairment of systemic venous return and may result in cardiovascular compromise Rarely, in patients with splinting of the mediastinum due to scarring (e.g. sequelae of tuberculosis) or malignancy, a 'tension' pneumothorax may occur without mediastinal shift

Figures 5A and B: (A) Chest radiograph (postero-anterior view) showing a left-sided pneumothorax (white asterisk), collapsed lung border (arrow) in a patient being treated for pulmonary tuberculosis. Parenchymal infiltrates in the right upper zone (black asterisk) are also evident, (B) Chest radiograph (postero-anterior view) showing a right-sided hydropneumothorax (asterisk); collapsed lung border (thin arrows) and a horizontal fluid level (thick arrow) are also seen.

Chest radiograph helps identifying underlying pulmonary parenchymal lesions and in differentiating pneumothorax from large emphysematous bullae and cysts of the lung.

Treatment

The therapeutic approach to the management of a patient with pneumothorax is shown in **Figure 6**. Tension pneumothorax is a medical emergency and requires immediate release of tension in the pleural space using a wide-bore plastic cannula connected to a water-seal drainage system. Tube thoracostomy, appropriate antibiotic therapy and/or anti-tuberculosis treatment may be necessary.

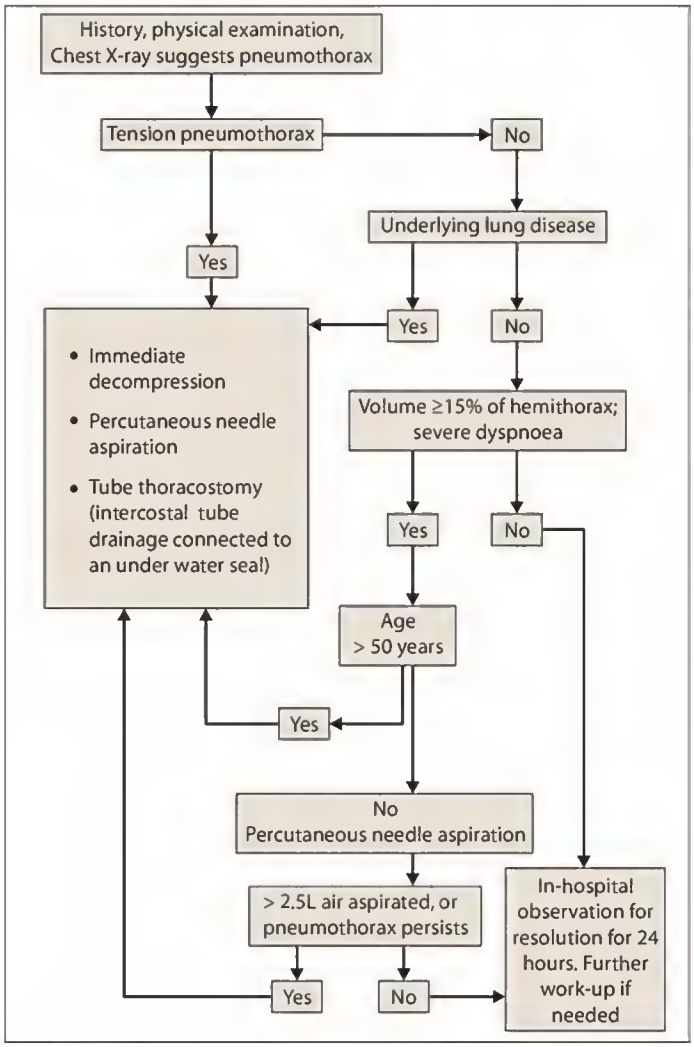


Figure 6: Algorithm for the management of a patient with pneumothorax.

Recurrent pneumothorax

Recurrent pneumothorax in individuals with a low respiratory reserve in whom further recurrence may be hazardous and in those indulging in activities such as flying or diving should be treated by surgical pleurodesis by pleural abrasion or parietal pleurectomy at thoracoscopy or thoracotomy.

TUMOURS OF THE PLEURA

Benign and malignant tumours of the pleura have been described. Metastatic tumours arising from primary tumours of the lung or breast are more common than primary pleural tumours.

Pleural Fibroma

Pleural fibroma is a benign tumour, most commonly encountered in middle-aged persons. The patients are usually asymptomatic and the tumour is incidentally diagnosed on chest radiograph taken for some other reason. Some patients may present with cough, breathlessness, chest pain and constitutional symptoms, such as fever and arthralgias. Digital clubbing and pulmonary osteoarthropathy are prominent features in some patients. Treatment is by surgical resection.

Malignant Mesothelioma

Aetiology

Asbestos exposure is strongly associated with the development of malignant mesothelioma. It occurs in the fourth or fifth decade of life; males are more frequently affected.

Clinical features

Salient clinical manifestations include chest pain, cough, fever, weight loss, anorexia and pleural effusion. Rarely, hoarseness of voice and dysphagia occur.

Diagnosis

The chest radiograph shows moderate to large unilateral pleural effusion or nodular or smooth unilateral pleural thickening. The CT of the chest may show a ring-like extension of tumour on the pleural surface. Diagnostic thoracocentesis, pleural fluid cytology, closed needle biopsy of the pleura, radiologically guided pleural biopsy may help in confirming the diagnosis. However, open biopsy at thoracoscopy or thoracotomy, electron microscopy and immunohistochemical staining may be required to distinguish malignant mesothelioma from metastatic adenocarcinoma.

Course and prognosis

The median survival time ranges between 4 months and 12 months from the time of diagnosis. Regardless of therapy, the prognosis is best for epithelial cell type. The sarcomatous cell type carries a poor prognosis; in the mixed or biphasic types, prognosis falls in between the two other types.

Treatment

Treatment includes surgical debulking (pleurectomy with decortication or extrapleural pneumonectomy) followed by chemotherapy and high-dose radiation therapy to destroy residual tumour cells.

DISEASES OF THE MEDIASTINUM

The mediastinum comprises the area between the two pleural sacs and is arbitrarily divided into anterosuperior, middle and posterior compartments (**Table 5**).

Acute Mediastinitis

Various causes of acute mediastinitis are listed in **Table 6**. Acute mediastinitis is usually secondary to spontaneous or iatrogenic perforation of a thoracic viscous (e.g. oesophagus); or after median sternotomy for cardiac surgery. Rarely, inhalational anthrax can cause primary acute mediastinitis. Patients with oesophageal rupture present with severe chest pain, breathlessness, and look acutely ill. Treatment includes parenteral antibiotic therapy, surgical exploration of the mediastinum and primary repair of the oesophageal tear, drainage of the pleural space and the mediastinum. Patients with mediastinitis following median sternotomy commonly present with wound drainage, sepsis or a widened mediastinum. Mediastinal needle aspiration confirms the diagnosis. Treatment includes parenteral antibiotics, immediate drainage, and debridement.

Table 5: Distribution of Lesions in Various Mediastinal Compartments

Mediastinal Compartment	Common Lesions	Rare Lesions
Antero-superior mediastinum The antero-superior mediastinum extends from the manubrium sterni and the first ribs to the diaphragm. Its posterior border is defined by the anterior aspect of the pericardium inferiorly and curves posteriorly to include the arch of the aorta and great vessels. This compartment encloses the ascending aorta, superior vena cava, azygous vein, thymus gland, lymph nodes, fat, connective tissue, transverse aorta and great vessels	Thymomas Lymphomas Germ cell tumours Lymph node TB	Vascular lesions Mesenchymal tumours Endocrine tumours
Middle mediastinum The middle mediastinum (visceral compartment) is bounded above by the superior pericardial reflection and below by the diaphragm. The posterior border extends to the spine. This compartment encloses the heart and pericardium, trachea and major bronchi, pulmonary vessels, lymph nodes, fat and connective tissue	Lymph node TB Foregut cysts Lymphomas	Pleural cysts Pericardial cysts Neuroenteric cysts Gastroenteric cysts Hydatid disease
Posterior mediastinum The posterior mediastinum (paravertebral compartment) extends from the superior aspect of the first thoracic vertebral body to the diaphragm anteriorly and then posteriorly to the posteriormost curvature of the ribs. It encloses the sympathetic chain, vagus nerves, oesophagus, thoracic duct, various lymph nodes and the descending aorta	Neurogenic tumours	Vascular lesions Mesenchymal lesions Lymphatic lesions

Table 6: Causes of Acute Mediastinitis

Oesophageal perforation
Instrumental (e.g. oesophagoscopy, sclerotherapy) Forceful vomiting (Boerhaave's syndrome)
Trauma
Foreign body
Operative injury
Caustic ingestion
Cancer
Tracheobronchial perforation
Direct extension of infection from retropharyngeal space; odontogenic infection (descending necrotising mediastinitis), pancreatitis, lung, pleura, pericardium, lymph node, paraspinal abscess
Post-sternotomy mediastinitis
Anthrax mediastinitis

Granulomaotus Mediastinitis and Mediastinal Fibrosis

Diseases such as TB, sarcoidosis, silicosis, histoplasmosis, and several other fungal diseases can cause granulomatous mediastinitis. Several conditions, such as drugs (e.g. methysergide), silicosis, multisystem fibrosing disorder, radiation, among others can cause fibrosing mediastinitis. These patients present with signs of compression of some of the mediastinal structures, like superior vena cava syndrome, tracheobronchial obstruction, compression of pulmonary vessels, or nerves.

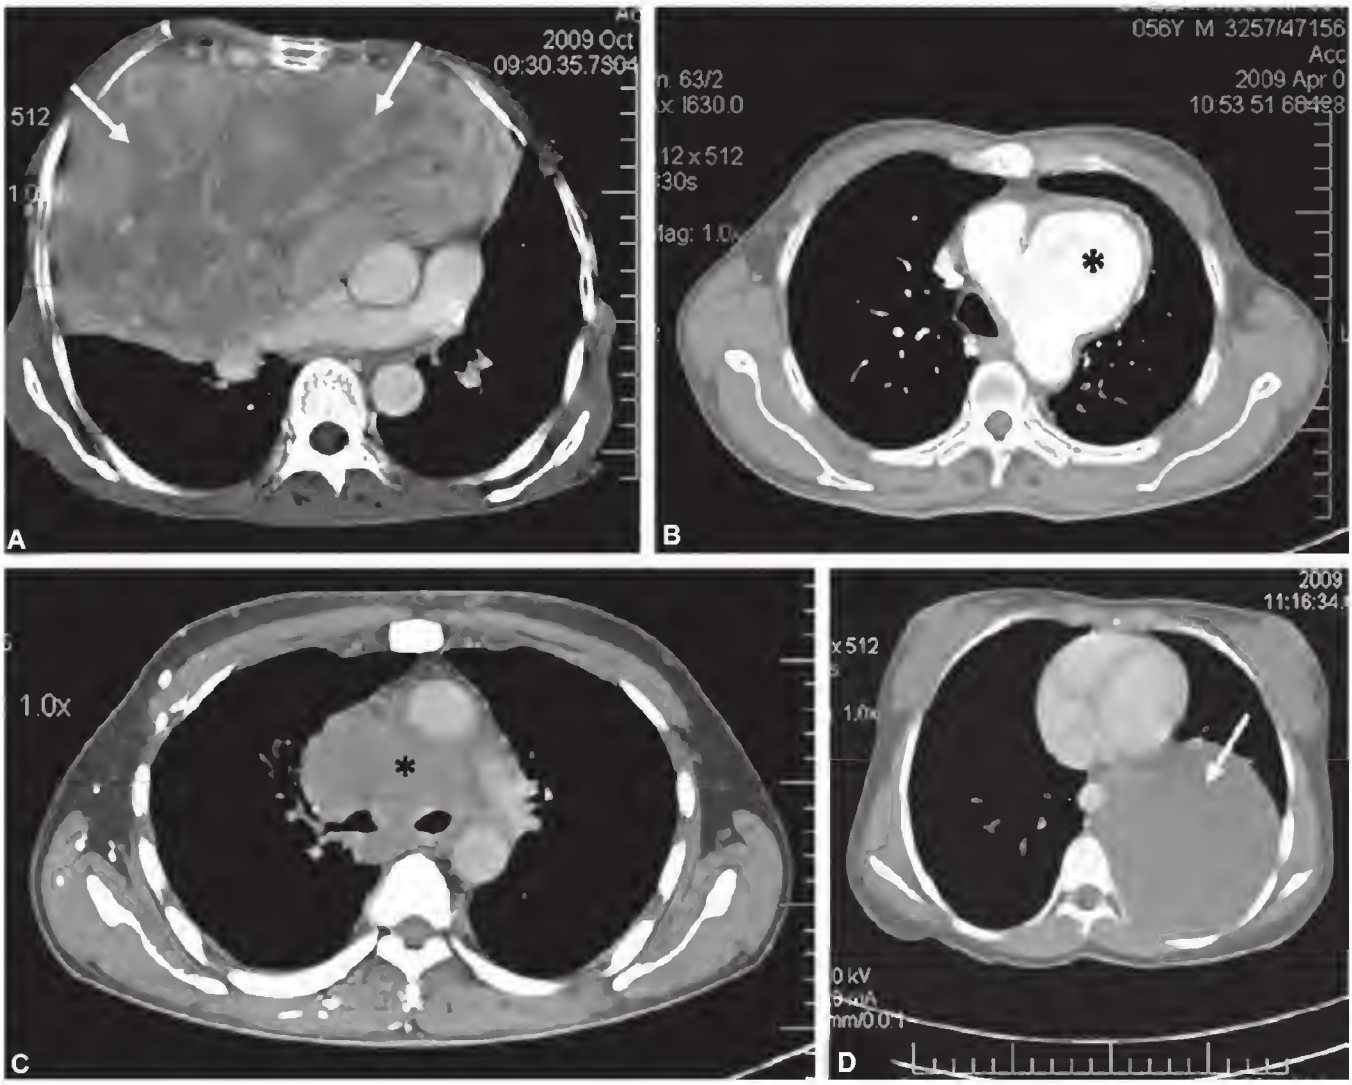
Pneumomediastinum

Presence of air in the interstices of the mediastinum is termed pneumomediastinum or mediastinal emphysema. Pneumomediastinum commonly results from microscopic alveolar rupture but can also be caused by air escaping from the upper respiratory tract, intrathoracic airways or gastrointestinal tract. Gas producing bacterial infection of the visceral space, outside air reaching the mediastinum following trauma or surgery are other mechanisms. Patients present with sudden severe pain in the substernal region and breathlessness. Subcutaneous emphysema in the suprasternal notch and a crunching or clicking noise synchronous with the heartbeat and best heard in the left lateral decubitus position (*Hamman's sign)* can be heard. The chest radiograph shows air in the mediastinum parallel to the heart and aorta. Treatment of the underlying disorder may provide relief from symptoms. Rarely, needle aspiration or surgical incision may be required to relieve mediastinal compression.

Mediastinal Cysts and Tumours

Mediastinal tumours (**Table 5**), (**Figures 7A to D**), when small, are asymptomatic and may be detected as an incidental finding on the chest radiograph. Patients may present with manifestations due to compression of various mediastinal structures by the mass. These include dyspnoea, cough, stridor, wheezing, haemoptysis, obstructive pneumonia and the middle lobe syndrome (compression of the trachea and the major bronchi); distended, non-pulsatile neck veins, oedema and cyanosis of face, neck and arms (*superior vena cava syndrome*); hoarseness of voice, bovine cough (left recurrent laryngeal nerve); diaphragm paralysis (phrenic nerve); dysphagia (oesophagus) and Horner's syndrome (sympathetic trunk). Patients of intrathoracic lymph node TB or lymphoma may present with systemic manifestations such as fever, weight loss and toxaemia. Chest CT is helpful in localising these lesions. Transthoracic needle biopsy, VATS or media-stinoscopy and biopsy help in confirming the diagnosis.

Thymic tumours



Thymoma is a common anterior mediastinal tumour and is frequently associated with *Myasthenia gravis* and pure red cell aplasia. Surgical resection is indicated as malignant thymomas are difficult to diagnose clinically.

Thyroid lesions

Mediastinal thyroid lesions include a cervical goitre, extending retrosternally into the anterior mediastinum and rarely, primary intrathoracic goitre. The lesion can be recognised by radioactive iodine scanning. Treatment is by resection.

Germ cell tumours

Germ cell tumours include teratoma and teratocarcinoma, seminoma, embryonal cell carcinoma and choriocarcinoma.

Figures 7A to D: (A) Contrast-enhanced CT chest (arrows) showing anterior mediastinal mass, (B) (asterisk) aortic aneurysm mimicking a middle mediastinal mass, (C) (asterisk) middle mediastinal lymph node mass, and (D) (arrow) a posterior mediastinal mass.

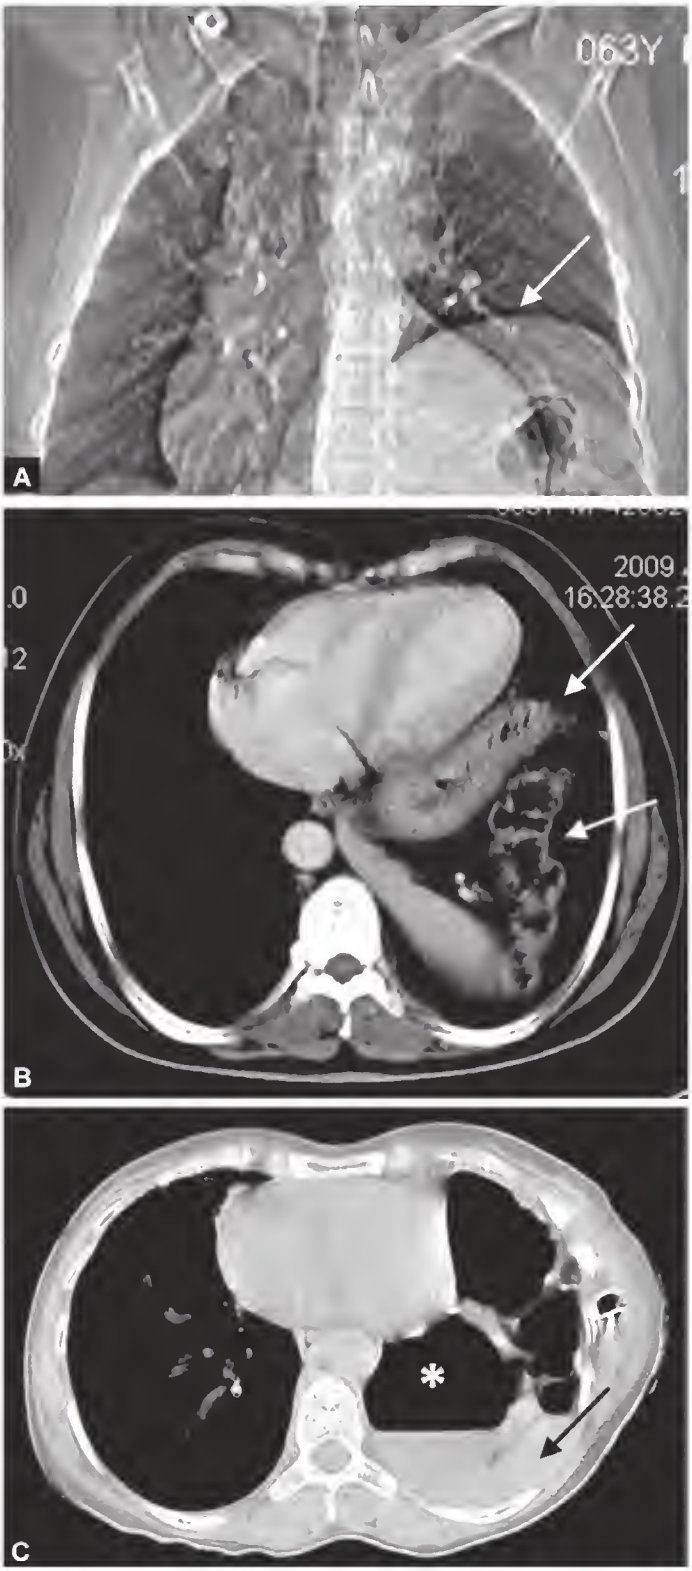
Teratomas, the most common germ cell tumours, are common in the anterior mediastinum. In teratomas, structures originating from all three germ cell layers may be found; ectodermal derivatives predominate. When only the epidermis and its derivatives are present, the lesion is termed dermoid cyst. Usually, they do not produce symptoms. Patients become symptomatic when infection sets in or malignant transformation occurs. Calcification is common and teeth may be identified. Chest CT is useful in delineating these lesions. Rarely, mediastinal seminoma and teratoma may be metastatic.

Neurogenic tumours

Neurogenic tumours are located mainly in posterior mediastinum. These tumours appear as dense, round or oval, radio-opaque densities occupying the paravertebral gutter on the chest radiograph. Many neurogenic tumours may be hormonally active.

Others

Rarely developmental cysts, such as, bronchogenic, pericardial or enteric cysts, hydatid cysts, primary carcinoma of the mediastinum, extra-medullary haematopoiesis in patients with chronic haemolytic anaemia can present as mediastinal tumours.



DISORDERS OF THE DIAPHRAGM

The diaphragm is the major muscle of respiration which separates the thoracic and abdominal cavities. Anatomical and neurological disorders affecting it render the diaphragm ineffective in providing adequate intrathoracic pressure resulting in a decrease in the amount of oxygen provided to the alveoli.

Anatomical Disorders

These can be congenital or acquired and result in diaphragmatic hernia. Bochdalek hernia results from herniation through a defect in the posterolaterally located Bochdalek foramen. Herniation thorough the foramen of Morgagni in the anterior midline through the sternocostal hiatus of the diaphragm is less common. Neonates with these conditions present with respiratory distress and need urgent surgical repair. In hiatus hernia, the abdominal contents herniate through the oesophageal hiatus. In sliding hiatus hernia, the gastro-oesophageal junction moves above the diaphragm together with part of the stomach. In rolling or para-oesophageal hiatus hernia, a part of the stomach herniates through the oesophageal hiatus and lies beside the oesophagus, without displacement of the gastro-oesophageal junction.

Eventration of diaphragm (**Figures 8A to C**) develops as a result of congenital or acquired decrease in muscle mass and increase in fibrous tissue and results in elevation of one hemidiaphragm (**Table 7**). Usually, most patients are asymptomatic and no treatment is required for this condition. Traumatic diaphragmatic rupture can occur due to both penetrating and blunt trauma and requires surgical intervention.

Figures 8A to C: (A) Contrast-enhanced CT chest topogram (arrow) and (B) transverse CT showing eventration of diaphragm (arrows), (C) Contrast-enhanced CT chest of another patient showing diaphragmatic hernia on the left side and the migration of stomach (arrow) and spleen (asterisk) into the left side of the thorax.

Table 7: Causes that Result in Elevation of the Diaphragm

Causes of elevation of one hemidiaphragm
Thoracic causes
Phrenic nerve palsy
Splinting of diaphragm (e.g. fractured rib, pneumonia, pleurisy)
Sub-pulmonic effusion
Post-operative (lobectomy, pneumonectomy)
Abdominal causes
Tumours, cysts and other causes of hepatomegaly
Amoebic liver abscess
Subphrenic abscess
Distended stomach
Interposition of colon between liver and right hemidiaphragm (*Chilaiditi syndrome*)
Elevation of both domes of diaphragm
Increased intra-abdominal pressure (e.g. obesity, ascites, pregnancy, abdominal tumours)
Spinal cord injury
Neuromuscular disorders

Disorders of Innervation

The transmission of respiratory stimulus from the brain to the diaphragm via the phrenic nerve can be interrupted by traumatic injury or disease processes, e.g. malignancy, spinal cord disorders, syringomyelia, poliomyelitis and motor neuron disease. Most patients with unilateral diaphragmatic paralysis remain asymptomatic. Bilateral diaphragmatic paralysis can present with severe exertional dyspnoea and marked orthopnea.

Evidence of paradoxical movement on performing the sniff test and observing the diaphragmatic movement on fluoroscopy or ultrasonography is a helpful manouevre in evaluating diaphragmatic paralysis and differentiating it from eventration of diaphragm.

DISORDERS OF THE CHEST WALL

The chest wall is a critical component of the respiratory pump and comprises of the bony structures (ribs, spine), respiratory muscles and nerves connecting the central nervous system with the respiratory muscles.

Several congenital abnormalities, such as pectus excavatum (funnel chest), *pectus carinatum* (pigeon chest) and *Poland's syndrome* (aplasia or hypoplasia of the sternocostal portion of the pectoralis major muscle, syndactyly), *Jeune's syndrome* (asphyxiating thoracic dystrophy) can impair chest wall function. In rickets, widening of the costochondral junctions (rachitic or rickety rosary), horizontal depression along the lower anterior chest (Harrison sulcus) due to pulling of the softened ribs by the diaphragm during inspiration may be seen. In scurvy, the sternum is depressed and scorbutic rosary can be seen. While rickety rosary is knobby and nodular, scorbutic rosary is more angular and has a step-off at the costochondral junction.

Chest wall cold abscess and sinuses can occur due to TB, thoracic actinomycosis. When an empyema goes undetected over a long period of time, it erodes through the chest wall, forms a subcutaneous abscess and spontaneously drains

on to the surface of the body and may present as a chest wall swelling with an expansile cough impulse (empyema necessitans).

Conditions causing kyphosis (spinal deformity with antero-posterior angulation) and scoliosis (lateral displacement or curvature of the spine) can result in severe rib distortion affecting the respiratory function. Fibrothorax as a result of underlying pleural or pulmonary disease also presents with the physiologic manifestations similar to those seen in chest wall disorders. Chest trauma can result in flail chest, usually due to sequential double rib fractures in more than one site or fracture of ribs and the sternum. Because of the rib fractures, there is uncoupling of a part of the chest wall from the rib cage resulting in paradoxical motion.

In ankylosing spondylitis, the anterior chest wall can be affected by enthesitis (inflammation of the muscular or tendinous attachments to bone) of the manubriosternal symphysis and sternoclavicular joints. Fixation of the chest wall through fusion of the costovertebral joints can also develop.

Chest wall tumours can present as a palpable mass with or without pain and systemic symptoms. Large tumours of the chest wall (**Figure 9**) can result in pulmonary restriction. Surgical excision is usually required.

Figure 9: Contrast enhanced CT chest of a patient showing a chest wall tumour (arrows) on the right side.

ACKNOWLEDGEMENT

The author wishes to thank the Department of Radiodiagnosis, Sri Venkateswara Institute of Medical Sciences, Tirupati, for providing the radiological images.

23.18 Atelectasis and Pulmonary Fibrosis

Rupak Singla

ATELECTASIS

The term atelectasis is derived from the Greek words *ateles* and *ektasis*, which mean incomplete expansion. Atelectasis is defined as diminished volume affecting all or part of a lung. Several types of atelectasis exist; each has a characteristic radiographic pattern and aetiology.

Classification and Pathophysiology

Atelectasis is divided physiologically into (a) obstructive and (b) non-obstructive.

Obstructive Atelectasis

Obstructive atelectasis, also known as resorptive atelectasis, is the most common type. It results from reabsorption of gas from the alveoli when communication between the alveoli and the airway is obstructed. The obstruction can occur at the bronchial or bronchiolar level. The most important condition producing intrinsic bronchial obstruction is bronchogenic carcinoma (**Table 1**). Other causes of bronchial obstruction include other primary lung and metastatic neoplasms, inflammatory aetiologies (especially tuberculous or fungal infection), aspirated foreign bodies, mucous plugging, a malpositioned endotracheal tube and extrinsic compression of an airway by neoplasm, lymphadenopathy, aortic aneurysm or cardiac enlargement.

Some conditions may decrease deep breathing or suppresses a person's ability to cough, such as large doses of opioids or sedatives, general anesthesia, chest or abdominal surgery, certain neurologic conditions, chest deformities, abdominal swelling, immobility of the body and some tight bandages. Such conditions can cause or contribute to atelectasis because of pooling of secretions, mucous or blood in bronchi. People who smoke or who have lung disorders (e.g. chronic obstructive pulmonary disease, cystic fibrosis) have a greater risk of developing atelectasis.

Following obstruction of a bronchus, the circulating blood absorbs the gas in the peripheral alveoli, leading to retraction of the lung and an airless state within a few hours. In the early stages, blood perfuses the airless lung; this results in ventilation-perfusion mismatch and arterial hypoxaemia. Filling of the alveolar spaces with secretions and cells may occur, thereby preventing complete collapse of the atelectatic lung. With passage of time, the uninvolved surrounding lung tissue distends, displacing the surrounding structures. The heart and mediastinum shift toward the atelectatic area, the diaphragm is elevated and the chest wall flattens.

The rate at which atelectasis develops and the extent of atelectasis depend on several factors. These include the extent of collateral ventilation that is present and the composition of inspired gas. The collateral ventilation is provided by the pores of Kohn and the canals of Lambert. The obstruction may lead to superadded infection in the atelectatic lung. If the obstruction is removed, any complicating post-obstructive infection subsides and the lung returns to its normal state. If the obstruction is persistent and infection continues to be present, fibrosis develops and the lung may become bronchiectatic.

Table 1: Causes of Atelectasis

- **Causes of obstructive atelectasis**
  - Causes within bronchial lumen
    - Neoplasm
      - Benign (adenoma)
      - Malignant (carcinoma bronchus, lymphoma, metastatic breast, thyroid, melanoma, sarcoma, seminoma, renal cell carcinoma, osteosarcoma, chondrosarcoma)
      - Alveolar cell carcinoma
    - Inflammatory aetiology (e.g. tuberculosis, fungal infection)
    - Aspirated foreign body
    - Mucous plug
    - Malpositioned endotracheal tube
  - Causes in the bronchial wall
    - Stricture or Stenosis
  - Causes outside the brochus
    - Neoplasm
    - Lymphadenopathy (hilar/mediastinal)
    - Aortic aneurysm or
  - Cardiac enlargement
- **Causes of non-obstructive atelectasis**
  - Relaxation atelectasis
    - Pleural effusion
    - Pneumothorax
    - Large emphysematous bullae
  - Compression atelectasis
    - Chest wall, pleural, or intraparenchymal masses
    - Loculated collections of pleural fluid
  - Adhesive atelectasis
    - Hyaline membrane disease
    - Acute respiratory distress syndrome
    - Smoke inhalation
    - Cardiac bypass surgery
    - Uraemia
    - Prolonged shallow breathing
  - Cicatrisation atelectasis
    - Idiopathic pulmonary fibrosis
    - Sarcoidosis
    - Pneumoconiosis
    - Collagen vascular diseases
    - Chronic tuberculous and fungal infections
    - Radiation fibrosis
  - Replacement atelectasis
    - Bronchoalveolar cell carcinoma

Non-Obstructive Atelectasis

Non-obstructive atelectasis can be caused by loss of contact between the parietal and visceral pleurae, compression, loss of surfactant and replacement of parenchymal tissue by scarring or infiltrative disease (**Table 1**). Subtypes of non-obstructive atelectasis are described below:

Relaxation or passive atelectasis

This results when a pleural effusion or a pneumothorax eliminates contact between the parietal and visceral pleurae. Generally, the uniform elasticity of a normal lung leads to preservation of shape even when volume is decreased. The different lobes also function differently, e.g. the middle and lower lobes collapse more than the upper lobe in the presence of pleural effusion, while the upper lobe may be affected more by pneumothorax.

Compression atelectasis

This occurs from any space-occupying lesion of the thorax compressing the lung and forcing air out of the alveoli. Such space-occupying lesions include pleural tumours, large pulmonary parenchymal masses, large emphysematous bullae and lobar emphysema. The mechanism is similar to relaxation atelectasis.

Adhesive atelectasis

This results from surfactant deficiency. The surfactant has phospholipid dipalmitoyl phosphatidyl-choline, which prevents lung collapse by reducing the surface tension of the alveoli. Lack of production or inactivation of surfactant, which may occur in adult respiratory distress syndrome (ARDS), radiation pneumonitis, or blunt trauma to the lung, causes alveolar instability and collapse leading to adhesive atelectasis.

Cicatrisation atelectasis

This results from diminution of volume as sequelae of severe parenchymal scarring. A number of conditions can result in pulmonary fibrosis and cicatrisation atelectasis, such as idiopathic pulmonary fibrosis, sarcoidosis, pneumoconiosis, collagen vascular diseases, chronic tuberculous and fungal infections, and radiation fibrosis.

Replacement atelectasis

This occurs when the alveoli of an entire lobe are filled by tumour (e.g. bronchioalveolar cell carcinoma) resulting in loss of volume.

Other Types of Atelectasis

Several other types of atelectasis observed in clinical practice are described below:

Right middle lobe syndrome

This is a disorder of recurrent or fixed atelectasis involving the right middle lobe and/or lingula. The right middle lobe, due to its anatomical separation from the upper and lower lobes and poor collateral channels of ventilation, collapses more frequently and rarely re-expands (Brock's syndrome). It can result from either extraluminal (bronchial compression by surrounding lymph nodes) or by intraluminal bronchial obstruction. It may develop in the presence of a patent lobar bronchus without identifiable obstruction. Inflammatory processes and defects in the bronchial anatomy and collateral ventilation have been designated as the non-obstructive causes of middle lobe syndrome.

Rounded atelectasis

This represents folded atelectatic lung tissue with fibrous bands and adhesions to the visceral pleura. Incidence is high in asbestos workers (65% to 70% of cases), most likely due to a high degree of pleural disease. The mean age at presentation is 60 years and the affected patients are typically asymptomatic.

Platelet atelectasis

This also called discoid or subsegmental atelectasis, this type is seen most commonly on chest radiographs. It probably occurs because of obstruction of a small bronchus and is observed in states of hypoventilation, pulmonary embolism or lower respiratory tract infection. Small areas of atelectasis occur because of inadequate regional ventilation and abnormalities in surfactant formation from hypoxia, ischaemia, hyperoxia and exposure to various toxins. A mild-to-severe gas exchange abnormality may occur because of ventilation-perfusion mismatch and intra-pulmonary shunt.

Post-operative atelectasis

This is a common pulmonary complication in patients following thoracic and upper abdominal procedures. General anaesthesia and surgical manipulation lead to atelectasis by causing diaphragmatic dysfunction and diminished surfactant activity. The atelectasis is typically basilar and segmental in distribution.

EPIDEMIOLOGY OF ATELECTASIS

The incidence and prevalence of atelectasis are not well documented. However, in India, cicatrisation atelectasis following tuberculosis (TB) is extremely common.

Age

The age at presentation depends upon the underlying cause. The mean age at presentation for rounded atelectasis is 60 years.

Sex

Atelectasis has no sex predilection.

Race

Atelectasis has no racial predilection.

Mortality/morbidity

Patient mortality depends on the underlying cause of atelectasis. In post-operative atelectasis, the condition generally improves. The prognosis of lobar atelectasis secondary to endobronchial obstruction depends on the treatment of the underlying malignancy.

CLINICAL PRESENTATION OF ATELECTASIS

Most symptoms and signs of atelectasis are determined by the rapidity with which the bronchial occlusion occurs, the size of the lung area affected, and the presence or absence of complicating infection. Rapid bronchial occlusion with large area of lung collapse causes pain on the affected side, sudden onset of dyspnoea, and cyanosis. Hypotension, tachycardia, fever and shock may also occur.

Slowly developing atelectasis may be asymptomatic or may cause only minor symptoms. Middle lobe syndrome often is asymptomatic, although irritation in the right middle and right lower lobe bronchi may cause a severe, hacking, non-productive cough.

PHYSICAL EXAMINATION OF ATELECTASIS

The physical examination findings show dullness to percussion over the involved area and diminished or absent breath sounds. Chest excursion in the area is reduced or absent. The trachea and the heart are deviated toward the affected side. A monophonic or fixed rhonchus may also be heard over obstructed atelectasis. In upper lobe collapse, these signs may be absent. In cases of post-obstructive pneumonitis, clinical findings of signs of volume loss with a dull note on percussion, tubular bronchial breath sounds, bronchophony, with coarse crepitations may be observed.

INVESTIGATIONS OF ATELECTASIS

Imaging Studies

Chest radiograph

Radiography is the initial investigation for suspected lung atelectasis. Chest radiographs show direct and indirect signs of lobar collapse. These have been described in **Table 2**.

Table 2: Radiographic Signs of Atelectasis

Direct Signs	
	Displacement of septa/fissure
	Loss of aeration leading to radio-opacity
	Crowding of bronchial and vascular markings
Indirect Signs	
	Elevation of hemidiaphragm
	Shift of trachea or mediastinum
	Narrowing of rib cage
	Over inflation of remaining lung
	Shift of hilum

Atelectasis of each segment or lobe of the lung results in a particular pattern of blurring of the normal boundaries (Silhouette sign) of mediastinal structures.

Upper lobe atelectasis may obliterate the superior mediastinal border. The collapsed right upper lobe shifts medially and superiorly, resulting in elevation of the right hilum and the minor fissure (**Figure 1**). Rarely, the right upper lobe may collapse laterally, producing a mass like opacity that may look like a loculated pleural effusion. The minor fissure in right upper lobe collapse is usually convex superiorly but may appear concave because of an underlying mass lesion. This is called the sign of 'Golden S'.

Figure 1: Chest radiograph (PA view) showing collapsed right upper lobe shifting medially and superiorly, resulting in elevation of the right hilum.

Middle lobe collapse obscures the right heart border (positive Silhouette sign) on a postero-anterior (PA) film (**Figure 2**). On lordotic view, a triangular opacity may be observed (**Figure 3**). The lateral view shows a triangular opacity overlying the heart because the major fissure shifts upward and the minor fissure shifts downward (**Figure 4**). On computed tomography, the atelectatic right middle lobe appears as a triangular opacity against the right heart border with the apex pointing laterally and is termed the 'tilted ice cream cone sign'.

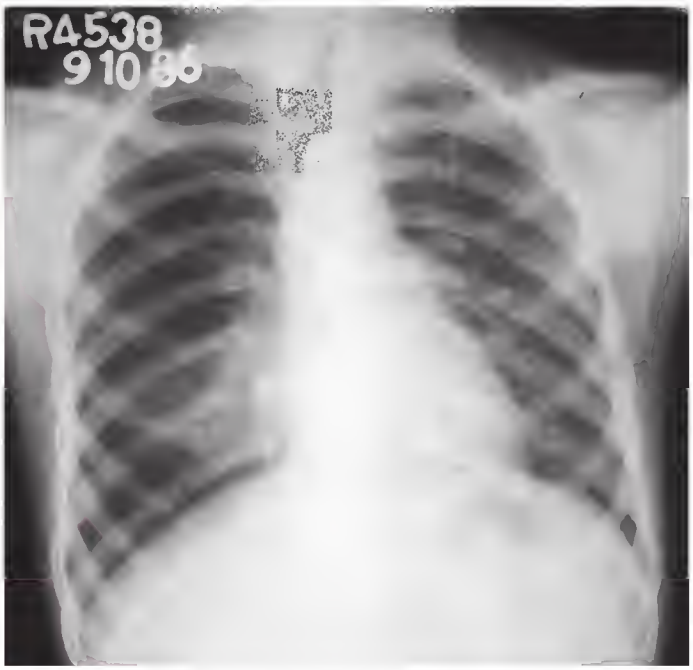

Figure 2: Chest radiograph (PA view) showing right middle lobe collapse obscuring the right heart border (positive Silhouette sign).

Figure 3: Chest radiograph (lordotic view) showing the right paracardiac triangular shadow suggestive of the right middle lobe atelectasis.

Lower lobe atelectasis does not obliterate the cardiac borders, and causes a retro-cardiac triangular opacity (**Figure 5**). On frontal views, the hilum shifts downward, and the rotation of the heart produces flattening of the cardiac waist, which is known as the

Figure 4: Chest radiograph (lateral view) showing a triangular opacity of right middle lobe atelectasis overlying the heart because the major fissure shifting upward and the minor fissure shifting downward.

Figure 5: Chest radiograph (PA view) showing the left lower lobe atelectasis seen as retro-cardiac triangular opacity.

flat-waist sign. On lateral radiographs, opacity makes the posterior third of the left diaphragm indistinct. A CT shows the atelectatic lower lobe in the inferior posterior location.

Complete atelectasis of a lung leads to opacification of the entire hemithorax and an ipsilateral shift of the mediastinum (**Figure 6**). In case of intraluminal growth, there may be sudden cut-off of air in the bronchus called 'bronchial cut-off sign' (**Figure 7**). The mediastinal shift separates atelectasis from massive pleural effusion.

Figure 6: Chest radiograph (PA view) showing complete atelectasis of the left lung leading to opacification of the entire hemithorax and an ipsilateral shift of the mediastinum.

Figure 7: Chest radiograph (PA view) showing sudden cut-off of air in the right main bronchus called 'bronchial cut-off sign'.

Computed tomography (CT)

CT is useful in evaluating the mediastinum, chest wall, hilum, pleura and adjacent lung. CT is also very sensitive for detecting the site of obstruction and whether a neoplasm is responsible for the same. In compressive atelectasis, air-bronchogram is present but not in obstructive atelectasis. CT may also be useful to

demonstrate associated bronchiectasis in chronic atelectasis. With the advent of spiral CT and three-dimensional reconstructions, virtual, three-dimensional images can be obtained and virtual bronchoscopy has become possible.

Magnetic resonance imaging (MRI): In some patients, MRI can provide comparable and/or complementary information.

Other imaging tests: In recent years, B-mode sonographic patterns as well as colour Doppler sonographic patterns of atelectasis have been reviewed. In addition, contrast-enhanced sonography (CES) allows differentiation between compression atelectasis and obstructive atelectasis by different patterns of enhancement.

Laboratory Studies

1. Pulmonary function testing in atelectasis of the lung usually shows a restrictive pattern. In some cases with associated bronchiectasis, a combined obstructive and restrictive pattern may be obtained.
2. On arterial blood gas analysis, atelectasis of a significant size may show hypoxaemia. However, despite hypoxaemia the $PaCO_2$ level is usually normal or low as a result of the increased ventilation.

Flexible Fiber-Optic Bronchoscopy

Flexible fiber-optic bronchoscopy (FOB) can be a useful diagnostic and therapeutic procedure.

1. Bronchoscopy helps in evaluating the cause of bronchial obstruction. In addition, bronchoscopy helps in clearing mucous plugs when they cause bronchial obstruction.
2. Bronchoscopy has its limitations. Because only the sub segmental bronchi are visualised, a distal end bronchial lesion is not accessible through bronchoscope.
3. In an evaluation of middle lobe syndrome, bronchoscope may show an endobronchial aetiology (mucus plugging/broncholithiasis/tumour), although the non-obstructive causes of the syndrome, such as inflammatory processes and defects in the bronchial anatomy and collateral ventilation may be missed.
4. During FOB, the washing, brushing and biopsy specimens of any obstructing mass should be examined for evidence of malignancy.

Complications of Atelectasis

Patients with atelectasis of lobe or segment of lung may have following complications:

1. Acute pneumonia
2. Bronchiectasis
3. Hypoxaemia and respiratory failure
4. Post-obstructive drowning of the lung
5. Sepsis
6. Pleural effusion and empyema

MANAGEMENT OF ATELECTASIS

Medical Care

The treatment of atelectasis depends on the underlying aetiology. Treatment of acute atelectasis, including post-operative lung collapse, requires removal of the underlying cause. In patients with pleural effusion, the pleural aspiration should be done and investigated for biochemistry and cytological examination. Tuberculosis should be treated with anti-tubercular drugs. In pneumothorax, intercostal tube drainage results in expansion of the lung. Immediate repositioning of the endotracheal tube will result in re-expansion of the lung in cases with inadvertent endotracheal tube of the right main bronchus. Large emphysematous bullae might require surgical resection. Chest physiotherapy and FOB might be helpful in patients with mucous plugging of the airways.

If a foreign body is suspected to be the cause for obstructive atelectasis, therapeutic bronchoscopy for its removal is indicated. In case of endobronchial tumour, the obstruction can be relieved by surgery, radiation or chemotherapy. In selected patients, laser therapy or airway stenting may be considered.

Non-pharmacologic therapies for improving cough and clearance of secretions from the airways include chest physiotherapy, including postural drainage, chest wall percussion and vibration, and a forced expiration technique (called huffing).

For post-operative atelectasis, prevention is the best approach by a good perioperative care. Anaesthetic agents associated with postanaesthesia narcosis should be avoided; narcotics should be used sparingly because they depress the cough reflex. Early ambulation and use of incentive spirometry are important. Encourage the patient to cough and to breathe deeply. Post-operative atelectasis is treated with adequate oxygenation and if required, by intubation and mechanical ventilatory support. When these efforts are not successful within 24 hours, flexible FOB should be performed.

In patients with chronic atelectasis, associated fibrosis, destruction and bronchiectasis can result in infection and haemoptysis. This can be prevented by regular chest physiotherapy and postural drainage, vaccines and antibiotics.

Surgical care

Chronic atelectasis with symptoms such as recurrent infections or significant haemoptysis is treated with segmental resection or lobectomy.

PULMONARY FIBROSIS

Pulmonary fibrosis describes the clinical end-point of a multiplicity of diverse pathological processes, ranging from infection to autoimmune diseases, most of which are of unknown aetiology but have characteristic features that allow them to be classified as distinct disease entities (**Table 3**).

Clinical Presentation of Pulmonary Fibrosis

Symptoms

By far, the most common presenting complaint of a patient of pulmonary fibrosis is dyspnoea. Depending upon the underlying cause, it may be acute, as in infections, extrinsic allergic alveolitis; sub-acute as in *Pneumocystis carinii* pneumonia associated with human immunodeficiency virus (HIV); or chronic as in asbestosis, pulmonary sarcoidosis. Cough is a fairly common symptom, and a very non-specific initial finding. Cough can be disabling, particularly in idiopathic pulmonary fibrosis (IPF) and diseases that primarily affect airways, such as bronchiolitis, cryptogenic organising pneumonia and sarcoidosis, in which cases it is also associated with expectoration. Other less common symptoms include chest pain and haemoptysis.

Table 3: Causes of Pulmonary Fibrosis

Post-infections	Drug-induced	Toxins/Poisons/ Organic Dusts	Occupational and Environmental
Post-TB Post-viral mycoplasma Human immunodeficiency virus-related	Nitrofurantoin, Bleomycin, Sulfasalazine, Beta-blockers, Gold, Penicillamine, Amiodarone, Busulfan, Methotrexate, Bromocriptine, Carmustine, Cyclophosphamide, Ergots, Nitrosoureas	Oxygen, Chlorine, Fluorine, Nitrogen dioxide, Paraquat radiation-induced, Fungal spores Animal proteins	Asbestosis Silicosis/Berylliosis Progressive massive fibrosis
Collagen Vascular Diseases	**Vasculitides**	**Inherited Causes**	**Idiopathic Causes**
Rheumatoid arthritis, Systemic lupus erythematosus Sjögren's syndrome Systemic sclerosis	Churg-Strauss syndrome Polyarteritis Nodosa Wegener's granulomatosis	Tuberous sclerosis Neurofibromatosis Ankylosing spondylitis Familial pulmonary fibrosis	Idiopathic pulmonary fibrosis Sarcoidosis Langerhan's cell histiocytosis Lymphangioleiomyomatosis, Amyloidosis Hemosiderosis

Table 4: Radiographic Pattern of Distribution of Pulmonary Opacities in Pulmonary Fibrosis

Upper Zones	Mid Zones	Lower Zones	Generalised
Pulmonary Koch's Sarcoidosis Langerhan's cell histiocytosis Silicosis Progressive massive fibrosis Extrinsic allergic alveolitis	Pulmonary oedema Alveolar proteinosis *Pneumocystis jirovecii* infection	Idiopathic pulmonary fibrosis Asbestosis Collagen vascular diseases Tropical pulmonary eosinophilia Rheumatoid lung disease Primary Sjögren's syndrome	Miliary tuberculosis, cystic fibrosis, metastases, acute respiratory distress syndrome, drug reactions, microlithiasis, lymphangitis carcinomatosis

Signs

Most common findings are crackles. These are usually inspiratory, and occur not only in most patients of pulmonary fibrosis associated with idiopathic pulmonary fibrosis, but also in many other interstitial lung diseases. The crackles are usually audible at the lung bases initially. Gradually, as the disease progresses, crackles extend upto the lung apices. In bronchiectasis, crackles may be inspiratory as well as expiratory.

Radiological Features

Tables 4 and 5 summarise the radiological features of pulmonary fibrosis.

Table 5: High Resolution Computed Tomography (HRCT) Features of Pulmonary Fibrosis

Cystic Disease	Honey-combing	Ground-glass Opacities
Langerhan's cell histiocytosis Lymphangio-leiomyomatosis	Asbestosis Collagen vascular diseases Chronic hypersensitivity Pneumonitis Sarcoidosis Idiopathic pulmonary fibrosis (IPF) End-stage acute respiratory distress syndrome	IPF Alveolar proteinosis Radiation pneumonitis Sarcoidosis

Complications of Pulmonary Fibrosis

Pulmonary fibrosis leads to the development of hypoxia, which in turn produces pulmonary arterial hypertension and right-sided heart failure. Supplemental oxygen therapy may prove beneficial.

Treatment of Pulmonary Fibrosis

As stated earlier, pulmonary fibrosis is an end-stage process and optimal therapy is an area of intense research. Supportive care, physiotherapy, and pulmonary rehabilitation are essentially required for all the patients. Supplemental oxygen inhalation may prove helpful for hypoxaemic individuals. Preventive strategies like vaccination with influenza and pneumococcal vaccines are useful to combat infection with these pathogens and should not be overlooked. Adequate counselling of patients regarding avoidance of exposure to likely offending drugs, toxins, occupational or environmental agents also form an important part of the treatment of pulmonary fibrosis. Corticosteroids and immunosuppressive therapy may be useful in relevant situations. Lung transplantation can be considered in end-stage fibrosis with an unfavourable prognosis.

23.19 Benign and Malignant Tracheobronchial Tumours

Lalit Kumar, MP Ram Prabhu

INTRODUCTION

Lung cancer is the most common cancer globally. During the past two decades, better understanding of the biology, use of systemic chemotherapy and development of biologic therapy for non-small cell lung cancer (NSCLC) has led to modest improvement in the quality of life and overall survival. Currently, adjuvant chemotherapy (4 cycles of platinum-based combination) is considered standard in completely resected NSCLC stage II and IIIA. Role of chemotherapy in resected stage IB NSCLC is not clear at present. Post-operative radiotherapy (PORT) is not indicated for stage I or II NSCLC, and remains controversial in resected stage IIIA (N2) disease. For advanced NSCLC, cisplatin-based doublets (two drugs) combination is preferred in patients with good performance status (ECOG,0- 1), whereas carboplatin-based combinations are preferred in patients with impaired organ functions (kidney, heart). Non-platinum cytotoxic doublets are acceptable for patients with contraindications to platinum therapy. Patients who fail to primary therapy benefit with docetaxel or pemetrexate or erlotinib. A small subset of patients with advanced NSCLC benefit with EGFR inhibitors—tyrosine kinase inhibitors, e.g. geftinib and erlotinib, though effect generally lasts for months. Benefit is seen predominantly in never-smokers, female patients with adenocarcinoma histology and in those with presence of activating mutations in the EGFR-TK domain. Currently, it is not clear if EGFR inhibitors should be used upfront or after chemotherapy or if they can be used as adjuvant in patients with early stage NSCLC. Another biologic agent, Bevacizumab (vascular endothelial growth factor inhibitor), when used with chemotherapy has been found to improve outcome in selected patients with non-squamous cell advanced NSCLC.

BENIGN TUMOURS OF TRACHEOBRONCHIAL TREE

Benign tumours of tracheobronchial tree are rare and account for 0.2% of all the respiratory malignancies (**Table 1**). Clinical presentation includes symptoms of airway obstruction like cough, shortness of breath or wheezing. Because of these non-specific symptoms, patients may be mistaken for asthma or obstructive lung disease and may receive oral corticosteroids, leading to delay in diagnosis. Some patients may also present with atelectasis and secondary pulmonary infection when tumour is detected incidentally. Haemoptysis can also be a presenting symptom.

The chest radiographs may demonstrate collapse of a lobe or an entire lung due to complete obstruction or to hyperinflation of the lung peripheral to a bronchial tumour that causes a ball valve effect. Computed tomography of the chest may demonstrate a tracheal or bronchial mass but it may underestimate the extent of submucosal invasion. Fibre-optic bronchoscopy is useful in: (i) directly visualising the tumour and its extent; and (ii) to take biopsy samples to clinch the diagnosis. Malignant tumours require further investigations to rule out distant metastasis.

Table 1: Benign and Malignant Tumours of Tracheobronchial Tree

Benign tumours of trachea and major bronchi
Bronchial mucous adenomas
Carcinoids
Pleomorphic adenomas
Malignant tumours of trachea and major bronchi
Mucoepidermoid carcinoma
Adenoid cyctic carcinoma
Squamous cell carcinoma
Bronchogenic carcinoma
Small cell lung cancer
Non-small cell lung cancer
Squamous cell carcinoma
Adenocarcinoma
Large cell carcinoma
Bronchoalveolar carcinoma
Other types: adenosquamous type, etc.

Carcinoid tumours are of neuroendocrine origin, found in large bronchi. Histologically, they are composed of cuboidal cells with small and hyperchromatic nuclei arranged in organoid or ribbon-like pattern. On immunohistochemistry, these cells stain positive for neuroendocrine markers like chromogranin and synaptophysin. Typical carcinoids have low mitotic rate with no necrosis. These tumours rarely metastasise. Atypical carcinoids, on the other hand, have higher mitotic activity and necrosis, and have poorer prognosis. Two per cent of bronchial carcinoids secrete serotonin and cause classical features of carcinoid syndrome—diarrhoea, flushing and hypotension. Some of them cause Cushing's syndrome by secreting ACTH.

Treatment of benign tumours consists of segmental resection of trachea or bronchus with or without sleeve resection of corresponding lung parenchyma. Unresectable malignant tumours are managed with radiotherapy or local ablative measures like laser photocoagulation or cryotherapy, although treatment in such cases is mostly palliative.

BRONCHOGENIC CARCINOMA

Lung cancer is the most common malignancy worldwide in males and is also the leading cause of death due to cancer. Almost half of the cases occur in the developing countries. Incidence of lung cancer is declining in industrialized nations (like United States) due to smoking control measures; it continues to rise in developing countries.

INDIAN SCENE

In India, lung cancer is the most common cancer among males (ICMR, 2005). Data from urban and rural population-based cancer registries is shown in (**Table 2**). The Cancer Atlas Programme of ICMR has revealed high incidence of lung cancer in certain pockets in north-east India. The median age at diagnosis is lower in India (54 versus 68 years), with higher male to female ratio (4:1 versus 1.4:1). Only 12% of patients had stage I-II

compared to 36% and squamous cell carcinoma is the predominant histological subtype (Table 3).

Table 2: Age Adjusted Incidence Rates of Lung Cancer in Population-Based Cancer Registries

Registry	Males	Females
Aizwal District	39.3	42.2
Mizoram State	24.9	24.7
Imphal West District	19.2	16.5

Small cell carcinoma	20	10
Large cell neuroendocrine	2	—
Others	12	25

RISK FACTORS

The various risk factors implicated in lung cancer are given in Table 4.

Smoking

Smoking is the most important risk factor for lung cancer especially for small cell lung cancer (SCLC) and squamous cell carcinoma. The relative risk of developing lung cancer is 30 times higher in smokers than in non-smokers. Only 5% to 10% of all patients with lung cancer are non-smokers. Tobacco smoke contains more than 300 chemicals, of which 40 are potent carcinogens. Nitrosoamines like nicotine-derived nitrosoamine ketone (NNK) and polycyclic aromatic hydrocarbons like benzo a pyrene can induce lung cancer in animal models similar to human lung cancer. Nicotine and inorganic metals like nickel, arsenic and chromium also act as carcinogens. The risk of lung cancer is directly related to the duration and intensity of smoking. Similarly, cessation of smoking is associated with decline in the risk of lung cancer. The relative risk is 16 after 5 years of cessation compared to non-smoker, 8 after 10 years and 2 after 30 years. Passive smoking also increases the risk of lung cancer. Studies indicate that it may contribute to 25% of all lung cancers in non-smokers.

Table 4: Risk Factors for Lung Cancer

- Smoking
- Industrial Carcinogens: accounts for up to 8% of lung cancer related deaths
  - Radionuclides such as uranium, radon in miners, radon derivatives (especially small cell lung cancer)
  - Asbestos, especially with heavy smoking; asbestos fibres include: actinolite, amosite, anthophyllite, chrysotile, crocidolite, and tremolite
  - Silica
  - Arsenic compounds: arsenic trioxide, arsenic pentoxide, arsenic acid and derivatives
  - Organic compounds like polycyclic aromatic hydrocarbons (PAHs), diesel fumes
  - Metals like nickel, chromium
- Fibrosis/Scars: Scars (scar carcinoma, cavitary lesions after tuberculosis) (cavitary carcinoma)
- Dietary Factors
- Genetic Predisposition
  - Risk in relatives of lung cancer patients is increased by factor 2-4
  - Chromosomal Deletions and Mutations: 3p21 deletion, mutations of tumour suppressor gene p53, and Rb, altered oncogene expression (myc in small cell lung cancer; K-ras, Her2/neu in adenocarcinomas)
  - Cytochrome P450
  - DNA repair genes like ERCC and XRCC
  - In East Asia, 40% of lung cancer cases occur in never-smokers and are associated with increased incidence of EGFR mutations.

Development of lung cancer is a multi-step process; initially there is epithelial metaplasia followed by dysplasia, carcinoma *in situ* and then invasive carcinoma.

PATHOLOGY AND CLASSIFICATION

The WHO histological classification of epithelial tumours of lung consists of 42 different histological varieties, but all these varieties can be grouped under two broad types: tumours originating from surface epithelium of bronchi or bronchioli, namely, non-small cell lung cancer and those arising from neuroectodermal cells/APUD (amine precursor uptake and decarboxylation), small cell lung cancer. Both these types differ in their cell of origin, histology, behaviour of growth and spread, natural course, staging and management.

The non-small cell lung cancers (NSCLCs) can be further subdivided into following types based on histological features although they do not differ in staging and treatment.

Squamous cell carcinoma was the most common type three decades ago; adenocarcinoma is currently the predominant type in industrialised nations. In India, squamous cell cancer is still the predominant histologic subtype (Table 3), there is marginal increase in the incidence of adenocarcinoma subtype. Squamous cell carcinomas typically arise from epithelium of proximal segmental bronchi, evolving through stages of squamous metaplasia, dysplasia, carcinoma *in situ* and invasive carcinoma and present as a hilar mass (Figure 1A). Figure 1B shows the CT image of same patient

Adenocarcinomas are typically located in the periphery of the lung and are less amenable to detection by sputum cytology or

Figure 1A: Chest radiograph showing right hilar mass with raised diaphragm.

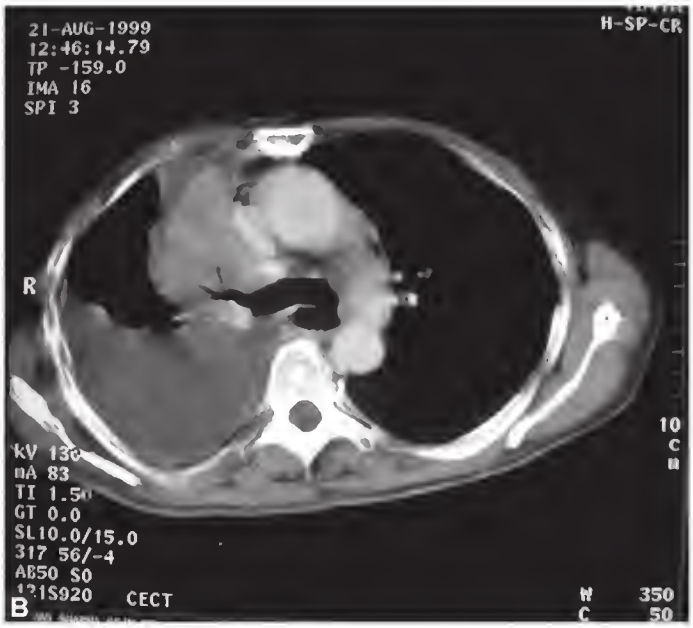

Figure 1B: Computed tomography of the same patient with evidence of right hilar mass and pleural effusion.

bronchoscopy but more approachable for CT-guided needle biopsies. Fourteen different subtypes have been described. Bronchoalveolar carcinoma is special subtype of adenocarcinoma seen more commonly in non-smoking females of Asian origin. This is multi-focal, spreads along the airways (known as lepidic spread) before stromal and angiolymphatic invasion and can hamper with gas exchange at alveolar surface causing dyspnoea. Mucinous variety can be associated with copious mucinous expectoration. Special interest has developed in this variety due to high incidence of epidermal growth factor receptor (EGFR) mutations and response to targeted therapeutic agents like erlotinib and gefitinib.

Large cell carcinomas comprise 15% of all lung cancers and present similar to adenocarcinomas as a peripheral lung nodule. Some of them show neuroendocrine differentiation and when associated with necrosis and high mitotic rate, are called large cell neuroendocrine carcinomas.

Lung cancer is a heterogeneous disease at molecular level. This is evidenced by the fact that a small subset of patients with advanced disease benefit with EGFR inhibitors – tyrosine kinase inhibitors (TKIs), e.g. geftinib and erlotinib, though effect generally lasts for months. Benefit is seen predominantly in never-smokers, female patients with adenocarcinoma histology and in those with presence of activating mutations in the EGFR-TK domain. The two most common mutations in the TK domain, exon 19 deletions and L858R have been associated with best responses. Similarly, pemetrexate is a newer antifolate drug and is effective for patients with advanced NSCLC with non-squamous histology.

MODE OF SPREAD

Lung cancer spreads locally by direct invasion of adjacent structures like chest wall, pleura, diaphragm, trachea, Oesophagus, and great vessels of mediastinum, pericardium and the heart. Lymphatic spread occurs to bronchopulmonary, mediastinal and subcarinal and then supraclavicular lymph nodes. Lower lobe lymphatics drain into posterior mediastinum and subcarinal nodes. Right upper lobe lymphatics drain towards the superior mediastinum and left upper lobe lymphatics drain into the anterior mediastinum as well as superior mediastinum.

Distant metastasis occurs to bone, liver, adrenals and brain and to any site in the body by haematogenous dissemination. Metastasis can also occur to the same lobe or other lobes or contralateral lung. Rare sites like skin and subcutaneous tissue, breast, ovary, testis and thyroid have been reported.

CLINICAL FEATURES

Cough is the most common symptom followed by breathlessness, haemoptysis and chest pain. Breathlessness may occur due to endobronchial obstruction by tumour causing collapse of a lobe or whole lung or pleural effusion. Rarely, breathlessness may be due to lymphangitis carcinomatosis, a condition where lymphatics are infiltrated by tumour (**Figure 2**). Haemoptysis occurs more often in a central lesion. Rapid enlargement of tumour, especially SCLC, can cause obstruction of SVC resulting in facial puffiness, plethora and engorged veins over the neck and chest wall together known as superior vena cava syndrome. Pancoast tumour is a lesion arising from the apical region of the lung (**Figures 3A and B**). It may cause Horner's syndrome due to involvement of sympathetic ganglia or its roots. Brachial plexus involvement may be seen.

Systemic symptoms like weight loss and loss of appetite are common. Symptoms may also occur due to metastatic lesions like bone pain in skeletal metastasis, painful and tender hepatomegaly in liver metastasis. Seizures and features of raised intracranial tension like headache, vomiting and papilloedema can occur in brain metastasis.

A unique constellation of symptoms can develop in lung cancer affecting the neuroendocrine system and skin caused by humoral substances released by tumour tissue, known as paraneoplastic syndromes. Clinical significance of paraneoplastic syndromes lies in the fact that they may precede cancer by months to years and may warn about occurrence. When they occur along with cancer, they may give a clue to underlying disease. Usually they resolve with treatment of the disease but some neurological syndromes may persist. Paraneoplastic syndromes are more commonly seen with SCLC but are also seen with NSCLC. The most common syndrome associated with SCLC is syndrome of inappropriate

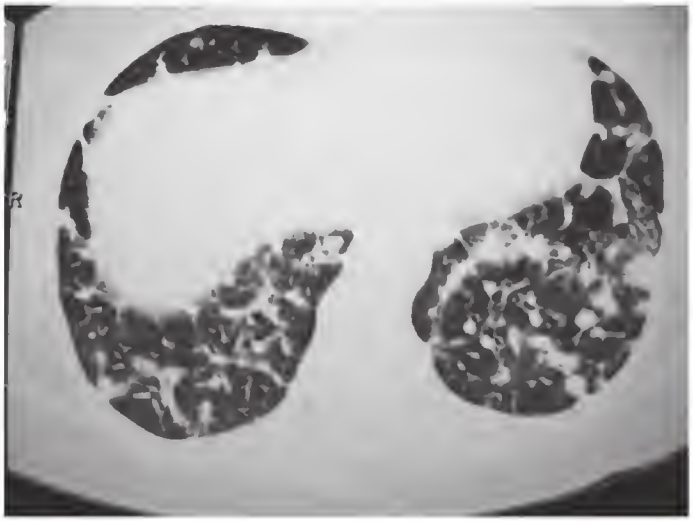

Figure 2: Computed tomography of the chest showing lymphangitis carcinomatosis.

secretion of anti-diuretic hormone (SIADH) resulting in hyponatraemia due to secretion of ADH by the tumour. Hyponatraemia is usually asymptomatic but can rarely cause neurological manifestations like seizures and altered mental status. Cushing's syndrome due to secretion of ACTH or corticotropin releasing hormone (CRH) has also been reported and portends a poor prognosis. Lambert-Eaton myasthenic syndrome is characterised by proximal muscle weakness which worsens with exercise. It can be differentiated from myasthenia gravis by electromyogram (EMG) and anti-cholinesterase antibodies. Peripheral neuropathy, limbic encephalitis and paraneoplastic cerebellar degeneration can occur in SCLC.

Hypercalcaemia is more common in squamous cell type of NSCLC. It is caused by secretion of parathyroid hormone related peptide (PTHrP) although hypercalcaemia due to extensive bone metastasis has to be ruled out. Clubbing and hypertrophic osteoarthropathy can occur in NSCLC. Thromboembolic manifestations can also occur. **Table 5** describes clinical features reported in major studies from India.

Table 5: Clinical Presentation: Experience from India (%)

	PGI Chandigarh (%)	AIIMS New Delhi N=907 (%)	Other Centres (%)
Cough with expectoration	88	83 (69.5)	40-94.3
Chest pain	52.2	78.9	16-66.7

Dysphagia	20.8	—	2.9-6
Others	30.5	—	—

SVCO = Superior vena cava obstruction.

INVESTIGATIONS

Complete blood count and renal and liver function tests along with electrolytes are recommended in all cases. Chest radiograph may reveal large peripheral lung nodule or central obstructing lesion, collapse or pleural effusion (**Figure 4**). Mediastinal lymphadenopathy and sometimes diaphragmatic palsy or lymphangitis carcinomatosa can be made out. Central lung lesion (near hilum) is mostly seen in small cell or squamous cell cancer. Peripheral lung lesions (distant to hilum, nodular structures) are frequently large cell lung cancer or adenocarcinomas. Diffuse lung disease is usually alveolar carcinoma.

Contrast-enhanced computed tomography (CECT) of chest and upper abdomen will pick up smaller lesions not visible on radiographs and also better define the anatomy of the lesion and its relation to mediastinal structures as well as lymph-adenopathy . It also reveals metastasis to other lobes, opposite lung, liver, or adrenals (**Figure 5**). CT scan has a sensitivity of 60% and specificity of 80% to detect lung cancer. FDG-PET scans ([^{18}F] Flouro-deoxyglucose-Positron emission tomography (FDG-PET scans) is useful in detecting mediastinal lymphadenopathy, visceral and bone metastasis. PET scan has higher sensitivity and specificity (70% and 80%, respectively) and high negative predictive value of 90%. Integrated PET-CT scans further improve sensitivity and specificity to 80% and 95%, respectively. MRI scans are not useful for diagnosis and staging but they may be useful in tumours invading spine, great vessels

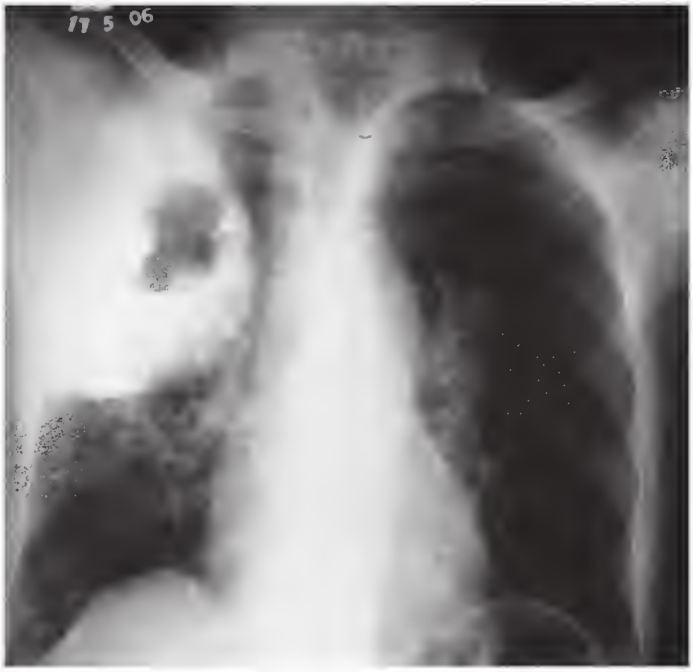

Figure 4: Chest radiograph showing mass lesion with evidence of cavity in squamous cell carcinoma.

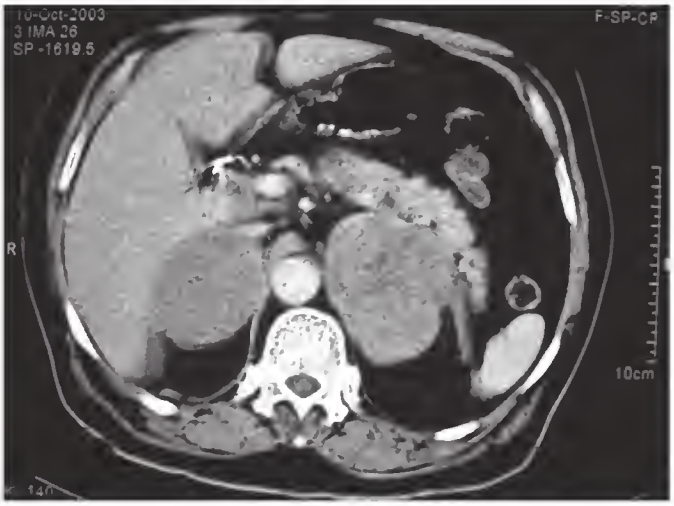

Figure 5: Computed tomography showing left adrenal metastasis.

or brachial plexus. MRI brain is superior to CT scan in detecting intracranial metastasis. Bone scan is used to detect skeletal metastasis.

DIAGNOSIS

Sputum cytology has a sensitivity of 65% in detecting lung cancer, especially in central lesions and with multiple sampling. Pleural fluid cytology helps in diagnosis in 60% to 70% of cases. CT-guided fine needle aspirate helps in diagnosing peripheral lesions with 95% yield. Sometimes, this technique is used to confirm solitary lesion in liver or adrenals. Fibreoptic bronchoscopy helps in visualising more central lesions and also to take biopsy or brush samples. Transbronchial aspirate of lung lesion or mediastinal lymph node can also be done. Video-assisted thoracoscopy (VAT) can be used in diagnosis, staging and interventional procedures like resection or mediastinal lymph node sampling. Mediastinoscopy is used to accurately stage the nodal disease. Thoracotomy and mediastinotomy are rarely performed due to availability of non-invasive imaging (CT and PET-CT) and less invasive procedures.

SOLITARY PULMONARY NODULE

Solitary pulmonary nodule is defined as an asymptomatic lung lesion less than 6 cm in diameter with normal physical examination and normal blood counts and liver function tests (**Figure 6**). It can be benign or malignant. Age greater than 45 years, history of smoking and a doubling time of 30 to 400 days indicate a high probability of malignant lesion. Circular, crescentric or densely calcified lesions are more likely to be benign. Suspicious lesions should be further investigated and the rest should be kept under follow-up. CT-guided needle biopsy yields an accurate diagnosis in 85% to 90% of the cases in peripheral lung lesions. Open biopsy is done in more central lesions. FDG-PET scans are considerably sensitive and specific in identifying malignant solitary pulmonary nodule.

Figure 6: Computed tomography of the chest showing speculated nodular lesion.

STAGING

TNM staging is used to define the extent of disease spread. Recently, International Association for the study of Lung Cancer (IALC, 2009) has proposed revised TNM staging. In this new classification, T1 tumours (0 to 3 cm) have been sub- classified as T1a (<2 cm) and T1b (2 to 3 cm); T2 tumours (>3 cm) to T2a (3 to 5 cm) and T2b (5 to 7 cm) and T2 tumours exceeding 7 cm as T3. Satellite nodule in the same lobe (T4) is now classified as T3 and additional nodules in a different ipsilateral lobe (M1) as T4 and additional nodules in contralateral lung as M1a, pleural and pericardial dissemination (T4) as M1a and distant metastases have been reclassified as M1b in the new staging system (**Table 6**).

TREATMENT

Surgery remains the treatment of choice for patients with stage I and II disease where the lesion is resectable. In Stage IIIA, ipsilateral mediastinal nodes are resectable but generally have a poorer outcome and post-operative adjuvant chemotherapy and/or radiotherapy is required. Stage IIIB lung cancers are unresectable in view of invasion of mediastinal structures or contralateral lymph nodes and stage IV disease is incurable by surgery due to distant metastasis. Resectability and operability has to be determined in each individual patient before planning surgery. Resectability indicates whether the disease can be excised without any residual disease. Some stage IIIA lesions

Table 6: TNM Staging of Non-Small Cell Lung Cancer by IASLC**

Primary Tumour	
TX	Tumour proven by presence of malignant cells in bronchopulmonary secretions but not visualised by imaging or bronchoscopy, or any tumour that cannot be assessed, as in pretreatment imaging
T0	No evidence of tumour
Tis	Carcinoma *in situ*
T1	Tumour ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, and without invasion proximal to a lobar bronchus at bronchoscopy
T1a	Tumour ≤2 cm in greatest dimension
T1b	Tumour >2cm but ≤3 cm in greatest dimension
T2	Tumour >3 cm but ≤7 cm in greatest dimension or tumour with any of the following features: involves the main bronchus ≥2 cm distal to the carina or invades the visceral pleura or associated with atelectasis/obstructive pneumonitis extending to the hilar region but does not involve the entire lung
T2a	Tumour >3 cm but ≤5 cm in greatest dimension
T2b	Tumour >5cm but ≤7 cm in greatest dimension
T3	Tumour >7 cm or of any size with invasion of any of the following: chest wall (including superior sulcus tumour), diaphragm, mediastinal pleura, parietal pericardium; or tumour in the main bronchus within 2 cm of the (but not involving) the carina; or associated atelectasis or obstructive pneumonitis of the entire lung; or separate tumour nodule(s) in the same lobe
T4	Tumour of any size with invasion of any of the following: mediastinum, heart, great vessels, trachea, oesophagus, vertebral body, carina; or separate tumour nodule(s) in a different lobe of the lung
Regional Lymph Node Involvement	
Nx	Regional lymph node status cannot be assessed
N0	No demonstrable metastasis to regional lymph nodes
N1	Metastasis to ipsilateral peribronchial and/or pulmonary or hilar nodes and intrapulmonary nodes (including direct extension)
N2	Ipsilateral mediastinal and/or subcarinal
N3	Contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular nodes
Metastasis	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Metastasis present
M1a	Separate tumour nodule(s) in a contralateral lobe; tumour with pleural nodules or malignant pleural (or pericardial effusion)
M1b	Distant metastasis

Stage Grouping			
IA	T1a, b	N0	M0
IB	T2a	N0	M0
IIA	T1a, b	N1	M0
	T2a	N1	M0
	T2b	N0	M0
IIB	T2b	N1	M0
	T3	N0	M0
IIIA	T1,T2	N2	M0
	T3	N1, N2	M0
	T4	N0, N1	M0
IIIB	T4	N0, N1, N2	M0
	Any T	N3	M0
IV	Any T	Any N	M1

are also unresectable. Operability indicates whether the patient is fit to undergo surgery. In general, patients should have normal haemogram, renal and liver function tests and optimal cardiopulmonary reserve which are determined by various modalities like spirometry with diffusion capacity, arterial blood gas analysis, echocardiography and ventilation-perfusion scans. If the post-operative predicted value of FEV_1 or DLCO equals or exceeds 40% of predicted, this is considered to be associated with lesser peri-operative risk. Lobectomy, bilobectomy or pneumonectomy can be performed depending on the extent of the disease. Post-operative mortality rates range from 6% for pneumonectomy to less than 1% for smaller resections.

Radiotherapy (RT) plays a role in locally advanced unresectable disease. External-beam radiotherapy from a linear accelerator is generally used after three dimensional CT planning. A dose of 60Gy to 66Gy is delivered to the primary lesion and 40 to 45Gy to the uninvolved lymph nodes over a period of 6 to 8 weeks when irradiated. Toxicity includes, acute complications like acute radiation pneumonitis (developing within 1 to 6 months of RT), acute oesophagitis and rarely pericarditis, myelitis and brachial plexopathy. Late complications include pulmonary fibrosis (<5%), oesophageal strictures and bronchial stenosis.

Chemotherapy when used alone is not curative in lung cancer but it improves survival when used along with primary modalities like surgery or radiotherapy. Adjuvant chemotherapy benefits patients of stage II and IIIA NSCLC. Neoadjuvant chemotherapy in which a specified number of cycles are administered before surgery or irradiation also appears to be beneficial. Concomitant chemoradiotherapy (CCRT) where radiotherapy is delivered along with chemotherapy has also been intensively investigated. The latter has been found to be beneficial, substantial toxicity has made people to prefer sequential chemotherapy followed by radiotherapy. Chemotherapy is the standard of treatment in stage IV disease. Intent is palliative in this setting. Platinum compounds like cisplatin and carboplatin have become the standard of care. Beside platinum compounds, other active chemotherapeutic agents include gemcitabine, taxanes (paclitaxel, docetaxel) and pemetrexate. The commonly used combinations are carboplatin and paclitaxel, cisplatin and paclitaxel, cisplatin and gemcitabine, and cispaltin and vinorelbine (**Table 7**).

Table 7: Common Chemotherapy Protocols for Non-Small Cell Lung Cancer and Small Cell Lung Cancer

Drugs	Dose	Route		
For non-small cell lung cancer				
Paclitaxel	175 mg/m²	IV	Day 1	Start next cycle
Carboplatin	AUC 6	IV	Day 2	on day 22
Gemcitabine	1000 mg/m²	IV	Day 1 & 8	Start next cycle
Cisplatin	70 mg/m²	IV	Day 1	on day 22
Vinorelbine	30 mg/m²	IV	Day 1 & 8	Start next cycle
Cisplatin	80 mg/m²	IV	Day 1	on day 22
Docetaxel	75mg/m²	IV	Day 1	Start next cycle
Cisplatin	75mg/m²	IV	Day1	on day 22
Second line				
Pemetrexate	500 mg/m²	IV	Day 1	Start next cycle on day 22
For small cell lung cancer				
Cisplatin	75 mg/m²	IV	Day 1	Start next cycle
Etoposide (VP-16)	100 mg/m²	IV	Day 1 to 3	on day 29
Second line				
Irinotecan	60 mg/m²	IV	Day 1,8,15	Start next cycle
Cisplatin	60 mg/m²	IV	Day 1	on day 29

Pemetrexed is a newer antifolate drug that has been approved as first-line treatment for patients with advanced non-squamous, NSCLC in combination with cisplatin, and as single agent for relapsed or chemotherapy refractory NSCLC after platinum-containing chemotherapy, at a dose of 500 mg/m^2. Pemetrexed undergoes intracellular activation by poly-gamma-glutamylation that is essential for its antiproliferative activity. Polyglutamate derivatives mainly inhibit three key enzymes of intracellular folate metabolism, i.e. thymidylate synthase (TYMS), dihydrofolate reductase (DHFR), and glycinamide ribonu-cleotide formyltransferase (GARFT), with TYMS being the most relevant target. Pemetrexed undergoes rapid renal elimination as unchanged parent compound, with a terminal half-life of between 2 hours and 5 hours. All patients on pemetrexate therapy should receive supplement-ation with folic acid and vitamin B12.

STAGE-WISE MANAGEMENT OF NSCLC

Stage I, II and IIIA patients should undergo surgical resection, if they are operable. Adjuvant chemotherapy is beneficial in stage II and IIIA disease. PORT (post-operative radiotherapy) has not been shown to be beneficial till now. Medically, inoperable early stage NSCLCs and unresectable locally advanced NSCLCs are treated with chemo-radiotherapy. A dose of 60 Gy to 70 Gy is administered in a daily fraction of 1.8 Gy to 2 Gy along with a platinum-based chemotherapy regimen. Chemotherapy and radiotherapy can be administered sequentially or concurrently. Concurrent administration has better outcome at the cost of excessive toxicity. Majority of the patients with NSCLC (55%) have stage IIIB or stage IV disease at presentation. Such patients have a median survival of 8 to 10 months with palliative chemotherapy and best supportive care. Chemotherapy helps in prolonging survival in patients with good performance status. In patients with poor performance status, chemotherapy has not been shown to be beneficial. The five-year survival in early operatable stages upto stage IIIA is 50% to 91% while it is less than 7% in late stage (stage IIIB/IV).

TARGETED THERAPY

Epidermal growth factor receptor (EGFR) mediates cancer cell growth, proliferation, invasion, metastasis and cell survival. EGFR is expressed in 40% to 80% of lung cancers making it an attractive target for molecular therapy. They bind to intracellular tyrosine kinase domain of the receptor and inhibit its activity. EGFR tyrosine kinase inhibitors (TKIs) like gefitinib and erlotinib are novel agents which have shown activity in NSCLC. They are especially found to be active in female gender, patients of Asian origin and in never-smokers. Bronchoalveolar subtype has been shown to respond to EGFR tyrosine kinase inhibitors. Mutations in EGFR gene are being studied to predict the response to EGFR TKIs. Side effects are skin rash, diarrhoea and rarely, interstitial pneumonitis. Cetuximab, a monoclonal antibody against EGFR, is also under clinical trial.

Tumour angiogenesis has been an important target in various cancers including lung cancer. Bevacizumab is a monoclonal antibody against vascular endothelial growth factor (VEGF), which is an important molecule mediating angiogenesis. It has shown activity in NSCLC in first-line setting when combined with standard chemotherapy.

PALLIATIVE TREATMENT

Endobronchial obstruction by tumours can be relieved by bronchoscopic removal either mechanically or by special techniques like laser ablation, electrocautery or cryotherapy. It may be followed by endobronchial stenting to prolong patency. Malignant pleural effusions which recur after multiple drainage can be managed by pleurodesis with talc, bleomycin, or doxycycline. Pericardial effusion can be relieved by indwelling catheters.

Radiotherapy can be administered for palliation of symptoms like haemoptysis, chest pain or dyspnoea. Haemoptysis can be controlled in 75% to 85% of patients with radiotherapy.

Bone Metastasis

Approximately 30% to 40% of NSCLC patients develop bone metastases. These are associated with a significant increase in skeletal-related events (SREs), including severe bone pain, hypercalcaemia, pathological fractures and spinal cord compression. These SREs result in impaired mobility, reduced quality of life, and frequently require therapeutic intervention (radiation therapy, surgery and systemic treatments). The normal balance of formation of new bone by osteoblasts and the resorption of old bone by osteoclasts becomes imbalanced and/or uncoupled, leading to the development of lesions that are osteolytic, osteoblastic or a combination of both. Palliative external-beam radiotherapy must be considered to relieve pain, unresponsive to narcotic analgesics. Bisphosphonate therapy (zoledronic acid) has proven efficacy for the treatment of bone metastases from a broad range of solid tumour types, including lung cancer. Symptomatic compression fractures in spine can be treated with vertebroplasty or kyphoplasty. Pathological fractures especially in weight bearing bones require orthopaedic fixation.

Brain metastasis, when solitary can be treated with surgical resection followed by whole brain radiotherapy (WBRT). Small lesions can also be treated with stereotactic radiosurgery using gamma knife. However, many patients present with multiple brain metastases in whom WBRT alone can be offered in addition to corticosteroids.

SMALL CELL LUNG CANCER (SCLC)

Small cell lung cancer constitutes 20% of all lung cancers and its incidence is probably declining in United States. In India, it accounts for 2.4% to 10% of all lung cancer types according to various hospital-based case series. It is strongly associated with smoking and occurs in the same age group as NSCLC. Incidence is higher in males. Clinically, it presents as a rapidly progressive lung mass, with dyspnoea, chest pain, and haemoptysis. They can present with symptoms due to metastasis like bone pain, abdominal pain or headache, vomiting or seizures in case of brain metastasis. SVC syndrome can occur in 10% of individuals. SCLCs usually present as a hilar or central mass and are usually metastatic at presentation (90%). Common sites of metastasis are liver, adrenals, bones (lytic or less commonly blastic lesions involving the vertebrae, ribs, pelvis , skull and long bones), bone marrow, and to brain.

Histologically, the tumour constitutes of dense sheets of small cells with scant cytoplasm, finely granular nuclear chromatin, inconspicuous or absent nucleoli. Frequent mitoses are seen.

Although histopathology is characteristic, immuno-histochemistry helps in difficult cases. Cytokeratin(CK) is positive and markers of neuroendocrine differentiation like CD56, synaptophysin and chromogranin can be demonstrated. TTF-1 is positive in 70% to 80% of the cases.

Only 10% of the patients with SCLC have disease confined to lung at presentation and surgery plays a limited role in SCLC. In contrast to NSCLC, SCLC has been staged into:

1. Limited stage disease
2. Extensive stage disease

Limited stage is defined as disease confined to one hemithorax that can be encompassed in a tolerable radiation field. Patients with ipsilateral malignant effusion, ipsilateral or contralateral supraclavicular lymph nodes or contralateral mediastinal lymph nodes are considered to have limited stage disease. Limited stage disease is treated with concurrent chemotherapy generally 4 to 6 cycles of cisplatin and etoposide(VP-16) and radiotherapy. In patients who may not tolerate concurrent chemo-radiotherapy, both can be given sequentially. Prophylactic cranial irradiation is given to patients who respond well to chemoradiotherapy in order to reduce the risk of brain metastasis.

Extensive stage disease is treated with chemotherapy alone. According to SEER programme database, 2-year and 5-year survival are 12% and 5%, respectively for extensive stage disease.

LUNG CANCER IN ELDERLY

Lung cancer in older patients (≥ 70 years) is an increasing problem. Elderly patients have comorbidities, and have poor tolerance to chemotherapy compared to younger patients. In elderly population of patients with advanced NSCLC, single agent chemotherapy with agents like gemcitabine, vinorelbine, and taxanes is considered standard therapy. Among targeted therapies, the EGFR inhibitors, e.g. erlotinib and geftinib, are most promising agents. Phase II data trials have shown activity and good tolerability in this population.

METASTATIC LUNG CANCER

Lung is the most common site for secondary metastasis. Tumours can spread to lung through haematogenous or lymphangitic routes. Lymphangitic spread occurs by retrograde spread from involved lymph nodes through lymphatic channels in the pleura and diaphragm and the thoracic duct to the mediastinal and the hilar lymph nodes. Widespread dissemination in the lung occurs through pulmonary lymphatics resulting in the picture of lymphangitis carcinomatosa (**Figure 2**). Typically seen in breast cancer and gastric cancer, lymphangitis carcino-matosa presents with progressive dyspnoea, chest signs of crackles and rhonchi in advanced or relapsed primary malignancy. Radiology reveals linear interstitial infiltrates especially in the lower zone and is better appreciated in computed tomography. Steroids and radiotherapy give some relief in symptoms but is ultimately fatal.

Haematogenous route is the more common mode of spread and arises from deposition of tumour cells and invasion of thin-walled capillaries. Breast, renal cell cancer, testicular germ cell tumours, gestational trophoblastic tumours-choriocarcinoma, osteogenic sarcoma and Ewing's sarcoma, soft tissue sarcomas, colorectal cancer, hepatocellular cancer, melanoma, thyroid and head, and neck cancers are common primary tumours to metastasise to lungs. In most cases, lung metastases are asymptomatic and detected as a new lesion in follow-up chest radiograph or computed tomography of chest in a patient with known malignancy. Frequently, lung metastasis is diagnosed along with primary during routine evaluation. Bulky tumour close to hilum or multiple florid metastases as that occurs in choriocarcinoma, renal cell cancer and testicular germ cell tumour can produce dyspnoea. Haemoptysis can occur in metastasis from choriocarcinoma. Pleural effusions or pleural deposits may be seen in some cancers like breast and ovarian cancer.

FOLLOW-UP

A regular follow-up is advised for patients treated with surgery, radiation and/or chemotherapy. On each visit, a detailed history, physical examination, chest radiograph and ultrasound are advised once in 3 months for first 2 years then once in 6 months till 5 years then once a year, indefinitely. For patients with advanced disease treated with palliative intent, symptom-based approach is advised for follow-up. Patients must be advised abstinence from smoking (and to avoid occupational exposure, wherever applicable).

CONCLUSION

More than 80% of lung cancer cases are attributed to smoking. While incidence of lung cancer is on the rise in developing countries, effective smoking control measures have shown a decline in its incidence in industrialised nations. Routine screening for lung cancer is not helpful. Newer diagnostic modalities like PET-CT and mediastinoscopy have improved diagnostic capability. Better understanding of molecular biology of lung cancer has led to development of targeted therapy and newer chemotherapeutic regimens. DNA from lung cancer cells has been sequenced with detection of 22,000 mutations. Identifications of key genes affected by mutations and development of targeted therapy would be important areas of research in future studies.

23.20 Cor Pulmonale

Sandeep Singh

DEFINITION AND EPIDEMIOLOGY

Cor pulmonale or pulmonary heart disease is a very popular term in medical literature but it has been used rather loosely for many years. It is best defined as an alteration in the structure or function of the right ventricle (RV) secondary to the diseases of lung or its vasculature. Pulmonary artery hypertension (PAH) is the link between the lung dysfunction and the involvement of the RV (hypertrophy and/or dilatation). Congenital heart diseases (CHDs) or primary abnormalities of the left side of the heart leading to PAH are not included in the definition of cor pulmonale.

An updated clinical classification of pulmonary hypertension (PH) has been developed by the experts at the Fourth World Symposium on Pulmonary Hypertension (Dana Point, California, 2008). This classification is considered to be the 'gold standard' today. The definition of cor pulmonale corresponds well with the group of 'pulmonary hypertension owing to lung diseases and/or hypoxia' as per this new classification.

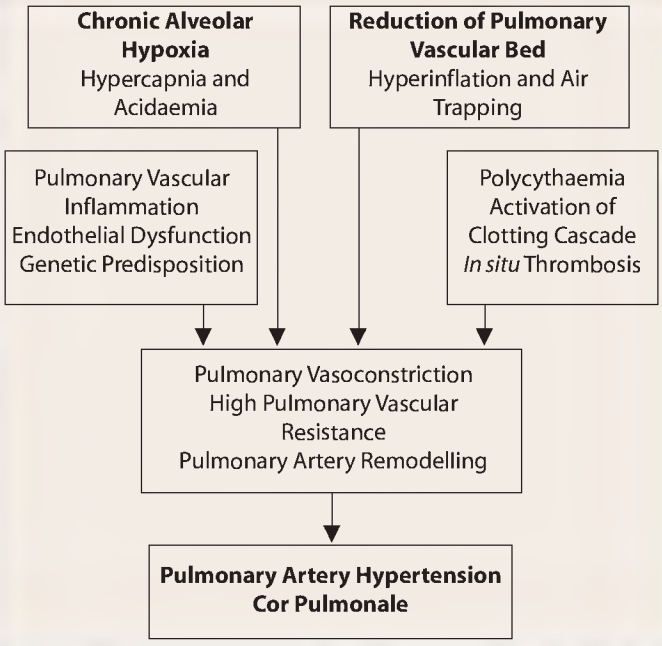
The true prevalence of cor pulmonale is difficult to ascertain as routine physical examination and non-invasive laboratory tests are relatively insensitive to confirm its diagnosis. PAH develops in approximately 25% of patients with advanced pulmonary disease. Cor pulmonale accounts for approximately 5% to 10% of all heart diseases and 20% to 30% of all admissions for heart failure (HF). The development of PAH has important prognostic implications, as it significantly increases the risk of hospitalisation and is associated with reduced survival.

AETIOLOGY

Many conditions can lead to cor pulmonale. **Table 1** provides a list of common diseases that may lead to cor pulmonale. The most frequent cause remains chronic obstructive pulmonary disease (COPD), which accounts for approximately 80% of the cases.

Table 1: Major Causes of Cor Pulmonale

Pulmonary diseases
Chronic obstructive pulmonary diseases
Pulmonary tuberculosis
Interstitial lung diseases
Bronchiectasis
Collagen vascular diseases
Sarcoidosis
Pneumoconiosis
Cystic fibrosis
Bronchiolitis obliterans
Drug-induced lung diseases
Disorders of chronic hypoventilation
Obesity hypoventilation syndrome
Neuromuscular diseases
Thoracic cage deformities
Sleep apnoea syndrome
Primary central hypoventilation



PATHOPHYSIOLOGY

PAH is defined as resting mean pulmonary artery pressure (PAP) of more than 20 mm Hg and during exercise more than 30 mm Hg. Typically, in patients with COPD, PAH appears when airflow limitation is severe and is associated with chronic hypoxaemia. In the initial stages, PAH may only be observed during exercise or sleep. Even in advanced stages, most patients have only modest increase in PAP at rest; the mean PAP varies between 25 mm Hg and 35 mm Hg. Rarely, severe PAH (mean PAP more than 35 to 50 mm Hg) may be observed, even without major airflow limitation. This is labelled as 'out-of-proportion' PAH, and carries poor prognosis with rapid progression to right HF and death.

This is in sharp contrast to the development of PAH due to left heart disease, CHDs, pulmonary thromboembolic disease and primary PAH, where mean PAP is usually more than 40 to 50 mm Hg.

Several pathophysiological mechanisms lead to PAH and subsequently cor pulmonale are shown in **Table 2**.

Table 2: Pathophysiology of Cor Pulmonale in Pulmonary Diseases

Pulmonary Vasoconstriction

Traditionally, chronic alveolar hypoxia is the most important factor leading to pulmonary vasoconstriction and an increased pulmonary vascular resistance (PVR). This hypoxic pulmonary vasoconstriction is an adaptive physiological response, shunting blood away from hypoxic regions to better ventilated parts of the lung. Hypercapnia and acidaemia further exacerbate pulmonary vasoconstriction that would result from a given level of alveolar

hypoxia. Eventually, chronic long-standing hypoxia induces structural changes in the pulmonary vascular bed leading to pulmonary vascular remodelling. In general, the more the abnormal in (PO_2) and (PCO_2) values in patients with COPD, the more severe the PAH and a greater likelihood of cor pulmonale.

Anatomical Factors

The destruction of the capillaries secondary to lung disorders [e.g. emphysema, interstitial lung diseases (ILDs), parenchymal infiltrative diseases] results in overall diminished cross-sectional area of the pulmonary vascular bed. This diminishment occurs progressively as the lung conditions deteriorate. In emphysema, there is destruction of capillaries that course along the alveoli that are being destroyed or coalescing to form bullae. Also, severe emphysema is associated with hyperinflation and air trapping, which results in positive alveolar pressure throughout the respiratory cycle. This causes mechanical compression on the surrounding vessels resulting in increased PVR. This mechanism perhaps assumes more importance in explaining the development of cor pulmonale in patients with severe emphysema who are not hypoxic. In ILDs, there is also decrease in distensibility of pulmonary vascular bed due to the surrounding fibrotic tissue causing higher PVR and PAH.

Haematological Factors

Increased blood viscosity secondary to polycythaemia, and activation of clotting cascade leading to *in situ* thrombosis. This further aggravates PVR.

Endothelial Dysfunction

It has been shown that in COPD there may be endothelial dysfunction resulting in imbalance between the mediators of vasodilation (nitric oxide, prostacyclin) and vasoconstriction (endothelin-1). There is reduction in synthesis and/or release of nitric oxide from the lungs. This is coupled with a reduction in prostacyclin synthesis and excessive expression of endothelin-1. All these factors lead to pulmonary vasoconstriction and higher PVR.

Genetic Predisposition

It has been proposed that pulmonary vascular response to hypoxia may be genetically predisposed. The expression of serotonin (5-hydro-xytryptamine, a potent pulmonary artery smooth muscle cell proliferator) and angiotensin (potent vasoconstrictor) are dependent on the polymorphism of 5-hydro-xytryptamine transporter and angiotensin-converting enzyme genes, respectively.

Inflammation

Role of inflammatory mediators has been increasingly accepted. It has been hypothesised that development of structural and functional abnormalities in COPD is related to inflammatory cells in the pulmonary vascular wall.

PATHOLOGY

The structural basis of chronic and sustained PAH in cor pulmonale include pulmonary vascular remodelling, reduction in cross-sectional area of pulmonary vessels and pulmonary *in situ* thrombosis. The structural changes particularly affect the distal pulmonary arteries and are characterised by medial hypertrophy of small pulmonary arteries, muscularisation of pulmonary arterioles, and initial thickening and fibrosis.

The increased PVR and PAH in cor pulmonale lead to sustained pressure over-load and eventually structural changes in the RV. There is gradual hypertrophy and dilation of right ventricle. Right HF sets in at a point when RV cannot meet the need for increased stroke work without significant increase in right heart filling pressures. This response depends upon the acuteness and severity of pressure over-load. Acute cor-pulmonale occurs after a sudden and severe increase in the after-load [e.g. massive pulmonary embolism (PE)], resulting in RV failure without RV hypertrophy. In comparison, chronic cor pulmonale is associated with more slowly progressive PH that leads to RV hypertrophy and dilation. Usually left ventricle (LV) is not involved in cor pulmonale. However, in advanced cases, the interventricular septum can get displaced towards the LV. This can cause reduction in the LV volume and cardiac output. This ventricle interdependence may play a role in cases with severe PAH and gross RV over-load.

CLINICAL FEATURES

Cor pulmonale has a chronic, long-standing, and slowly progressive course. However, at times acute worsening of stable cor pulmonale with life-threatening complications may occur. This acute decompensation occurs either from the progression of underlying disease or a superimposed acute process causing additional stress on the RV. The precipitating event for decompensation is often a respiratory tract infection.

The clinical detection of cor pulmonale is often difficult due to subtle and non-specific signs and symptoms. Early stages of PH may not have any additional clinical finding. Even later, symptoms suggestive of an underlying pulmonary disease dominate. These include dyspnoea on exertion, chronic cough and expectoration, wheezing, and occasional cyanosis and clubbing of fingers. In addition, patients with severe PAH may experience fatigue, dizziness, or even effort-related syncope. This occurs due to the lack of rise in the cardiac output during exercise. Angina chest pain may be seen due to RV ischaemia or pulmonary artery stretching. Rarely, grossly-enlarged pulmonary artery can cause hoarseness of voice due to compression of the left recurrent laryngeal nerve. In advanced stages, right HF occurs resulting in symptoms similar to that ensues in chronic HF. These include anorexia, right upper quadrant discomfort, ascites, and pedal oedema. Symptoms of left heart involvement in the form of orthopnoea and paroxysmal nocturnal dyspnoea are usually absent. Orthopnoea, when present in patients with isolated right HF reflects an increased work of breathing in the supine position due to compromised excursion of the diaphragm.

The physical examination detects findings of PH and RV hypertrophy. Patients with right HF have tachycardia, tachypnoea, elevated jugular venous pressure (JVP), hepatomegaly, and pedal oedema. Sometimes, pedal oedema may be seen even without right HF. The mechanisms include peripheral vasodilatation associated with hypercapnia, renal vasoconstriction secondary to hypoxia causing sodium retention, and neurohormonal activation.

Cardiovascular examination may reveal prominent 'V waves' in JVP as a result of tricuspid regurgitation. In addition, there may be a prominent 'a wave' reflecting the increased force of right atrial contraction. The RV heave may be palpable along the

lower left sternal border or in the epigastrium. The pulmonic component of the second heart sound is accentuated and may even become palpable. The second heart sound may be narrowly split. Right-sided S3 or S4 gallop may be present. A high-pitched pulmonary systolic ejection sound may be heard in the second and the third left intercostal spaces next to sternum. This is often followed by a soft, localised systolic ejection murmur produced by ejection of the RV stroke volume into a dilated pulmonary artery. Often, tricuspid regurgitation is present resulting in blowing pansystolic murmur in the lower left sternal border which increases with respiration (Carvallo's sign). When prominent PH is present, a soft, decrescendo diastolic murmur of pulmonary incompetence (Graham Steell murmur) may be heard that localised to the second and the third left parasternal area. It must be remembered that all these clinical findings may get masked due to hyperinflation and increased anteroposterior diameter of the chest in patients with advanced COPD.

DIAGNOSIS

Due to the non-specificity of the symptoms and signs, ancillary evaluation may be useful. Pulmonary function data using spirometry is mandatory for the diagnosis of COPD; however, it is not useful in predicting PAP. The common investigations necessary in patients of cor pulmonale include the following:

Chest Radiograph

The findings of chest radiograph largely depend on the underlying pulmonary disease. Characteristic features of PAH include enlargement of central pulmonary arteries and hilar vessels. The peripheral vessels are attenuated in advanced cases resulting in oligemic peripheral lung fields. A right descending pulmonary artery with a diameter greater than 16 mm suggests PAH. The heart may have globular appearance due to the RV enlargement (**Figure 1A**). Some encroachment of the retrosternal space by the enlarged RV may be seen in a lateral view (**Figure 1B**). If hyperinflation of lungs is marked, the overall cardiac silhouette may not be enlarged. In advanced cases, when RV failure sets in, there may be right atrial and RV dilatation on chest radiography.

Electrocardiography

Unfortunately, electrocardiogram (ECG) findings are insensitive for detection of PAH. Only one-third of patients with elevated PVR have signs of cor pulmonale on ECG. There may be right atrial enlargement (p-pulmonale) in severe cases. This results in an increase in amplitude of P wave in lead II, III, aVF to more than 2.5 mm. The QRS vector in the frontal plane often shifts to the right. If lung hyperinflation is present, a low voltage QRS complex is common. Incomplete or complete right bundle branch block may be seen. RV hypertrophy which exhibits tall R waves in lead V1 (**Figure 2**) and prominent S wave in lead V5 and V6 may be seen. In acute cor pulmonale, such as occurs in acute PE, a classical pattern of S wave in lead I and a Q wave and inverted T wave in lead III ($S_1Q_3T_3$) may be seen.

Computed Tomography

A high-resolution computed tomography (CT) of the chest is useful in accurately diagnosing early emphysema and ILDs. Contrast-enhanced CT of the chest is very useful for diagnosing acute PE. Ventilation-perfusion lung scan remains useful for the diagnosis of chronic pulmonary thromboembolic disease.

Figure 1A: Chest radiograph (postero-anterior view) showing globular shaped heart due to right ventricle enlargement, prominent main and right descending pulmonary artery due to pulmonary artery hypertension.

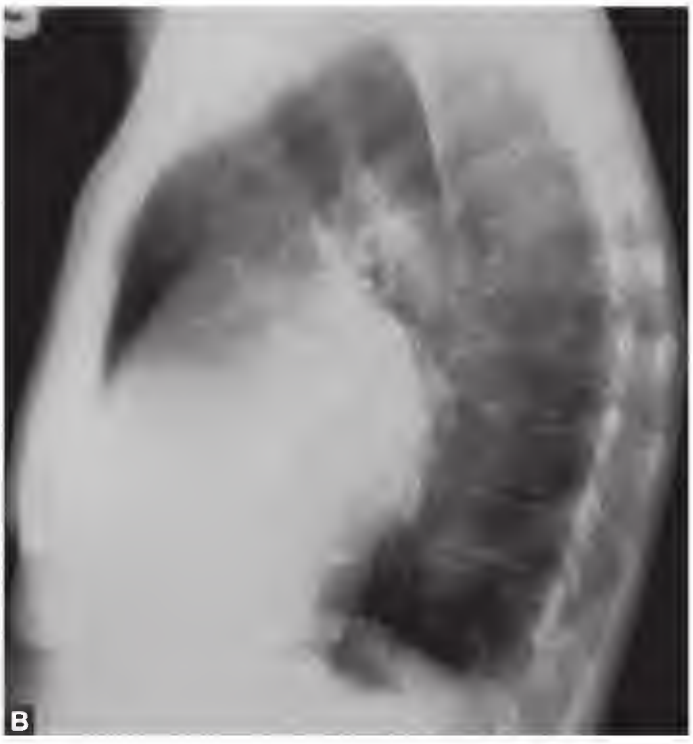


Figure 1B: Chest radiograph (lateral view) showing encroachment of retrosternal space due to right ventricle enlargement.

Echocardiography

Echocardiography is an invaluable tool in the evaluation of most forms of PAH. However, its utility may get limited in patients with COPD because of suboptimal images. Echocardiographic examination also assists in eliminating various non-pulmonary causes of PH, such as LV dysfunction from coronary artery disease or dilated cardiomyopathy, aortic or mitral valve disease and CHD. Two-dimensional echocardiography is useful for measuring right atrium and RV dimensions (**Figure 3**). RV wall thickness as well as its contractility can be assessed. There may be paradoxical movement of interventricular septum into LV

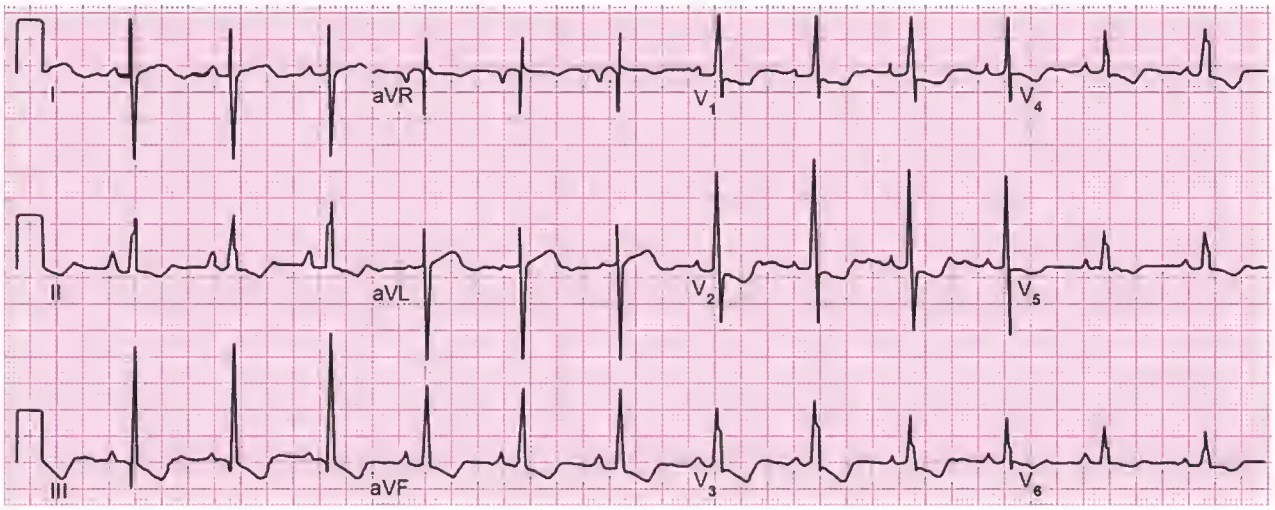

Figure 2: Electrocardiography showing right atrial enlargement (p-pulmonale), right axis deviation and right ventricle hypertrophy.

during systole. At a later stage, dilatation of the tricuspid annulus and RV leads to tricuspid regurgitation. Inferior vena cava may be dilated.

Figure 3: Two-dimensional echocardiography showing enlargement of the right ventricle.

Doppler echocardiography is the best and most reliable method for non-invasive diagnosis of PAH. It allows estimation of the PAP by measuring the jet velocity of tricuspid regurgitation using continuous wave Doppler echocardiography. If sufficient lung hyperinflation prevents an adequate trans-thoracic examination, trans-oesophageal echocardiogram may be useful.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) allows the measurement of volumes and blood flow in the thorax. It may be useful for assessing RV structure and function, particularly in patients who are difficult to image with echocardiography because of severe lung disease. However, its role as a routine diagnostic tool to diagnose PAH in patients with pulmonary diseases needs to be defined.

Right Heart Catheterisation

Catheterisation of the right heart is the 'gold standard' for the diagnosis and quantification of PAH. The haemodynamic definition of PAH includes a mean PAP $\geq$20 mm Hg, with a pulmonary capillary wedge pressure (PCWP) or LV end-diastolic pressure $\leq$15 mm Hg and calculated PVR $\geq$3 Wood units.

It is very useful for excluding the elevated left heart pressure (measured as the PCWP) as a cause of right HF. However, it is an invasive procedure and its use cannot be recommended routinely.

Cardiac Bio-Markers

Natriuretic peptides are released by cardiac myocytes. B-type natriuretic peptide (BNP) and N-terminal BNP levels are elevated in patients with cor pulmonale secondary to RV stretch and may be dramatically elevated in acute PE. Given the high sensitivity of these peptides for moderate to severe PAH, their measurement is recommended.

TREATMENT

The primary treatment must be directed to the specific underlying pulmonary condition leading to cor pulmonale. This chapter focuses on the treatment of cor pulmonale secondary to COPD. General principles of medical treatment includes decreasing the work of breathing by assisting ventilation, use of bronchodilators, steroids as well as treatment of any underlying infection. In the management of chronic cor pulmonale, diet and lifestyle modifications play an important role. These include smoking cessation, salt restriction, and weight loss. Structured pulmonary rehabilitation programmes have been useful. Patients with severe PAH, especially if there is history of syncope, should avoid over-exertion. Blood transfusion is indicated in anaemic patients. Phlebotomy should be performed in patients with severe polycythaemia (haematocrit $\geq$65%). This results in reduction in PVR and PAP and improvement in exercise tolerance.

Oxygen Therapy

Long-term oxygen therapy (LTOT) has convincingly shown to improve the pulmonary haemodynamics in patients with COPD.

Adequate oxygenation relieves pulmonary vasoconstriction and reduces PVR and RV after-load. The RV contractility is improved leading to an increase in its stroke volume and cardiac output. Renal vasoconstriction is also relieved, resulting in an increase in urinary sodium excretion. There is improvement in oxygen delivery to brain, heart, and other vital organs.

Two landmark, prospective randomised trials evaluated the pulmonary haemodynamics in patients with COPD using LTOT. In the British Medical Research Council (MRC), oxygen administration for at least 15 hours a day prevented further rise in PAP. Similarly, in the USA, nocturnal oxygen therapy trial (NOTT), administration of continuous oxygen resulted in favourable pulmonary haemodynamics and improved survival as compared to only nocturnal oxygen therapy. Further, the results of many small scale studies also support that the LTOT convincingly attenuates the progression of PAH. It may even reverse the PAH, however, the PAP seldom returns to normal. The longer the daily duration of oxygen therapy, the better are the pulmonary haemodynamics in these patients. Accordingly, continuous oxygen therapy is strongly recommended.

However, it must be emphasised that at times acute administration of high concentration of oxygen to hypoxic COPD patients can adversely affect breathing, especially if there is hypercapnia. These patients need to be observed more closely in the initial phase of domiciliary oxygen therapy to ensure that the ventilatory drive is not being impaired.

Today, three systems: gas cylinders, liquid oxygen systems, and oxygen concentrators are available for delivery of LTOT at home. Of these, the most attractive is the oxygen concentrator which extracts pure oxygen from the room air and provides a constant supply of oxygen. Recent advances in their designs have made these devices portable as these weigh less, easy to carry and store, and the oxygen supply lasts longer.

Diuretics

Diuretic therapy is the mainstay in the management of chronic cor pulmonale with excessive RV over-load. It alleviates dyspnoea, hepatic congestion, and peripheral oedema. It decompresses the RV by reducing the pre-load, reducing in the ventricle wall stress, and improved myocardial performance. Potentially, reduced shift of interventricular septum towards LV improves LV filling and systemic cardiac output. However, excessive volume depletion should be avoided, since significant contraction in the RV filling volume and pressure in the setting of PH may reduce cardiac output. Another potential complication of diuretic therapy is the development of metabolic alkalosis. This suppresses the ventilation and can result in worsening of hypercapnia.

Digoxin

It is of uncertain benefit in the management of cor pulmonale. Its effects on the RV are unclear. Clinical studies do not support its routine use in patients with cor pulmonale. If needed, it should be given in low doses and monitored carefully. It must also be emphasised that patients with COPD are particularly sensitive to its use. It can result in serious arrhythmias in the setting of hypoxia, acidosis, and electrolyte imbalance.

Pulmonary Vasodilators

These agents have been largely studied in the setting of primary PAH (idiopathic PAH) or PAH secondary to connective tissue disorders. No large scale studies or guidelines are available for their use in patients having PAH secondary to pulmonary diseases.

Inhaled nitric oxide is more potent vasodilator than oxygen. However, if used alone, it worsens ventilation-perfusion imbalance. Also, the delivery of nitric oxide and the cost are potential obstacles for its use. The phosphodiesterase-5-inhibitors (sildenafil), prostacyclin and its analogues (epoprostenol) and endothelin receptor antagonist (bosentan) are specific pulmonary vasodilators and have been successfully used in idiopathic PAH, scleroderma and chronic pulmonary thromboembolic disease. It may be possible that in future, these drugs may be used synergistically with LTOT in patients with cor pulmonale secondary to pulmonary diseases.

PROGNOSIS

Before the widespread availability of LTOT, development of PAH in COPD patients doubled the mortality. However, even with LTOT, the 5-year survival is approximately 30% to 35% with mean PAP >25 mm Hg as compared 60% to 65% in those whose initial pressures are <25 mm Hg. Those patients who develop severe PAH (mean PAP >40 mm Hg) suffer extremely poor prognosis with approximate 5-year survival of 15%.

24.1 Basic Considerations of Rheumatology

Rohini Handa

Musculoskeletal (MSK) complaints are frequently encountered in clinical practice. Pain is the most common presenting manifestation. Since a wide variety of conditions may give rise to MSK pains, a systematic approach is necessary to arrive at a diagnosis. Patient history is the single most important source of diagnostic information, followed by a careful physical examination. Laboratory investigations play a supplementary role, rather than primary role. Several MSK diseases resemble each other at the outset and a definitive diagnosis may not be possible at the first patient visit. A distinctive pattern may become discernible only over a period of observation. In such a situation, symptomatic treatment without rushing to give a specific label and close follow-up are quite appropriate.

APPROACH TO A PATIENT WITH MUSCULOSKELETAL COMPLAINTS

The three key points that need address are origin of pain, nature of disease, e.g. inflammatory or non-inflammatory, and pattern recognition.

Origin of Pain (Articular or Non-Articular)

The first task of the clinician who is confronted with MSK pains is to ascertain the exact source of pain by history and examination (**Figure 1**). Not all pains around a joint originate in the joint itself. Adjacent periarticular structures such as bone, ligament, tendon, bursa, or muscle may be responsible (**Table 1**). In general, articular pains tend to be diffuse and deep seated. In contrast, the pain of bursitis is characterised by localised point tenderness away from the joint line. Active (patient moves the joint himself/herself) and passive (physician puts the patient's joint through range of motion) movements also help in making this distinction on the bedside. Articular pain is aggravated by both active and passive movements in contradistinction to periarticular pain, which is more aggravated by active than passive movements. Mechanical symptoms like locking, instability or 'giving way' point to articular origin of pain. The clinician has also to be aware of the possibility of 'referred pain'. For example, hip pain may be referred to the knee.

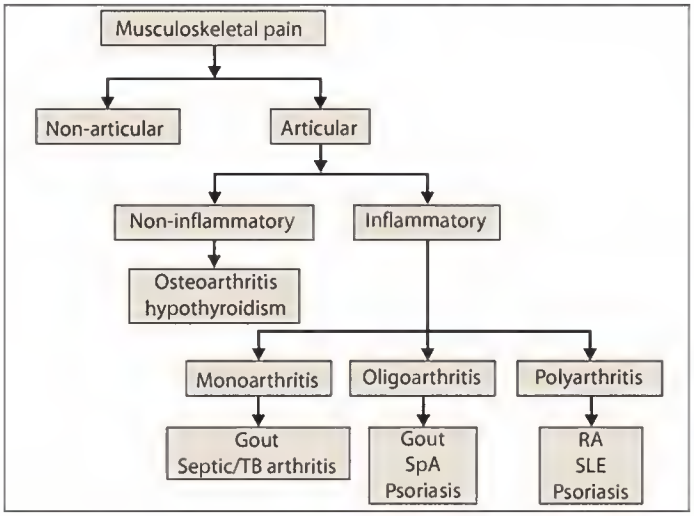

Figure 1: Approach to a patient with musculoskeletal pain.

SpA = Spondarthritides; RA = Rheumatoid arthritis; TB = Tuberculosis; SLE = Systemic lupus erythematosus.

Table 1: Identifying the Site of Musculoskeletal Pain

Arthritis	Joint swelling and tenderness Pain often diffuse, deep seated Pain increases on both active and passive movements
Bursitis	Point tenderness over the anatomical site Pain more on active than passive movements
Tendinitis	Linear, tender swelling of tendon sheath Stretching the tendon induces pain Tendon rub may be palpable/audible
Enthesitis	Pain at tendon insertion site Characteristic feature of spondarthritides
Bone pains	Deep seated Tenderness can be elicited by pressing bones
Muscle pains	Diffuse, not well localised Tenderness on squeezing muscles
Fibromyalgia	Diffuse pain with characteristic tender points
Growing pains	Benign leg pains, typically bilateral, in children of 8-12 years age; usually a diagnosis of exclusion

Arthralgias should be differentiated from arthritis. Arthralgias are joint pains without obvious inflammation; whereas, arthritis is associated with demonstrable features of inflammation like joint swelling and tenderness. Raised temperature and visible redness are usually not seen in chronic arthritides like rheumatoid arthritis (RA) or spondarthritides (SpA). These are more a feature of conditions like acute gout or septic arthritis. Arthralgias are non-specific and seen in several non-MSK conditions, e.g. haematological diseases, post-viral fever, metabolic arthropathy like hypothyroidism, etc. A drug history may be important because some commonly used drugs like statins can cause MSK symptoms.

Nature of Disease (Inflammatory or Non-Inflammatory?)

One of the fundamental concepts in rheumatology is to differentiate inflammatory rheumatic diseases like RA, SpA, lupus, etc. from non-inflammatory disorders like osteoarthritis (OA) since the management is radically different. Inflamed joints stiffen or 'gel' after periods of inactivity and tend to loosen with use. In contrast, non-inflammatory or mechanical joint pain improves with rest and is typically associated with use related pain. **Table 2** outlines the points that help in clinical differentiation. It has to be borne in mind that even patients with inflammatory joint disease can develop mechanical symptoms, for example, secondary OA of knees in a patient with RA.

Table 2: Differentiating Inflammatory from Non-Inflammatory Rheumatic Diseases

	Inflammatory rheumatic diseases	Non-inflammatory rheumatic diseases
Examples	RA, SpA, SLE	OA, trauma, hypothyroidism
Morning stiffness	> 30 minutes	< 30 minutes
Pain aggravation	On resting the joint	On moving the joint
Spontaneous flares	Common	Uncommon
Acute phase reactants like ESR, CRP	Increased	Normal

RA = Rheumatoid arthritis; SpA = Spondarthritides; SLE = Systemic lupus erythematosus; ESR = Erythrocyte sedimentation rate; CRP = C-reactive protein.

Pattern Recognition

Joint pains are a near universal feature of rheumatic or MSK diseases. However, other features like chronology, number/type/sequence of joints affected, symmetry, presence or absence of fever, extra-articular involvement, etc. give rise to a distinctive pattern that helps in making a diagnosis (**Table 3**). For example, an inflammatory polyarthritis in a young woman that is associated with fever and malar rash is highly likely to be lupus. Similarly, an insidiously developing arthritis associated with Raynaud's phenomenon and skin thickening and tightening suggests a diagnosis of systemic sclerosis (SSc). It is worthwhile to remember that on occasions, especially at disease onset, the symptoms and signs may not fit into any one pattern, when the term 'undifferentiated' arthritis is used. Over a period of time, the disease may resolve, evolve into a definitive entity or stay 'undifferentiated'. It is because of this reason that management decisions in rheumatology are based on organ involvement rather than diagnostic labels. Often, features of two or more MSK diseases may be present in the same patient when the term 'overlap syndrome' is employed. The various features that aid pattern recognition are discussed below:

Table 3: Pattern Recognition in Musculoskeletal Diseases

Mode of onset
- Acute
- Insidious

Duration
- Acute or self-limited
- Chronic

Number of affected joints
- Monoarthritis
- Oligoarthritis
- Polyarthritis

Distribution
- Symmetrical or asymmetrical
- Lower limbs versus upper limbs
- Small versus large joints
- Specific joints

Extra-articular features
- Fever
- Mucocutaneous lesions
- Eye
- Nodules

Sequence of involvement
- Intermittent
- Additive
- Migratory

Chronology

The mode of onset and duration of symptoms help in differential diagnosis. Acute onset is seen with septic arthritis, reactive arthritis, viral arthritis, gout or trauma. On the other hand, conditions like RA, SpA and OA tend to be insidious in onset. Based upon duration, MSK complaints may be classified into acute (lasting <6 weeks) or chronic (lasting >6 weeks). Patients with acute, self-limited conditions like viral arthritis may require only a limited evaluation and follow-up. However, patients with symptoms lasting >6 weeks need detailed evaluation. Other groups of patients who merit detailed evaluation irrespective of symptom duration are patients with prominent constitutional/systemic symptoms, e.g. fever, weight loss etc., older patients and patients who exhibit multiple organ involvement.

Number of joints affected

Arthritides are divided into monoarthritis (single joint involvement), oligoarthritis (affecting 2, 3 or 4 joints, also known as pauci-articular disease) and polyarthritis (affecting ≥ 5 joints). The important conditions in each category are listed in Table 4. It is important to know the number of joints affected because it narrows down the diagnostic possibilities, and helps the clinician in embarking upon investigations in a planned manner. Involvement of a single joint should prompt the clinician to consider crystal arthropathy (like gout) or septic arthritis. A good rule of the thumb is to consider every case of monoarthritis as infection of the joint unless proven otherwise. Joint aspiration and synovial fluid analysis are mandatory. Overlooking septic arthritis is a serious error because delay in treatment rapidly results in joint destruction. Synovial fluid should be subjected to gross examination, total and differential leucocyte counts, Gram and Ziehl-Neelsen staining, culture, and crystal studies. Protein and sugar estimations in synovial fluid, unlike CSF or pleural/peritoneal fluids are of no value. Tests for mucin, clot and viscosity are no longer performed. Polymerase chain reaction (PCR) for *Mycobacterium tuberculosis* in synovial specimens can be associated with false positives and should never be interpreted in isolation from clinical findings. The normal synovial fluid has a cell count less than 200 WBCs/mm^3, mostly mononuclear. The cell count in non-inflammatory conditions like OA is less than 2000 WBCs/ mm^3 while the count in inflammatory conditions like RA and gout is >2000 WBCs/ mm^3. Septic arthritis is associated with very high counts in range

Table 4: Differential Diagnosis Based on Number of Joints Affected

Monoarthritis	Oligoarthritis	Polyarthritis
Septic arthritis	Gout	Rheumatoid arthritis
Tuberculous arthritis	Juvenile idiopathic arthritis (JIA)	Psoriatic arthropathy
Gout and other crystal deposition diseases	Psoriatic arthropathy	SLE Systemic sclerosis
Spondarthritides	Spondarthritides	Juvenile idiopathic arthritis
Monoarticular presentation of polyarticular disease		Adult-onset Still's disease Inflammatory bowel disease Gout (rarely)

of 100,000/mm³ with >90% polymorphonuclear leucocytes. Synovial fluid crystal identification is the gold standard for diagnosis of gout and other crystal arthropathies.

The SpA constitute the vast majority of oligoarthritides encountered in clinical practise. It is a big group of inter-related conditions where ankylosing spondylitis is the prototypic illness. Other disease entities in SpA include reactive arthritis (including Reiter's syndrome), psoriatic arthropathy, arthritis associated with inflammatory bowel disease and undifferentiated SpA. Clinically SpA should be suspected whenever a young patient less than 40 years (males outnumber females) presents with inflammatory low back pain and asymmetrical, lower limb, large joint oligoarthritis, i.e. asymmetric involvement of hips, knees or ankles. While dealing with low backache (LBA), it is clinically helpful to differentiate between mechanical and inflammatory low backache. Mechanical causes comprise more than 90% cases of LBA. Inflammatory LBA, a typical feature of SpA, worsens after rest or prolonged sitting in the same posture, in contrast to mechanical causes like prolapsed intervertebral disc which improve on rest. Early morning stiffness, buttock ache, enthesitis, dactylitis, peripheral joint synovitis and eye involvement, if present, support the diagnosis of SpA. Sacroiliitis is the characteristic radiologic hallmark of SpA. HLA B27 is present in a varying proportion of patients with SpA depending on the underlying condition. However, HLA B27 can be present in healthy individuals also. The presence of HLA B27 does not mean SpA and conversely, the absence of HLA B27 does not rule out SpA.

Gout presents most often as monoarthritis, less commonly as oligoarthritis and rarely as polyarthritis. JIA and psoriasis can cause both oligoarticular and polyarticular joint disease. Spondarthritides are characterised by inflammatory low back pain in addition to arthritis.

Another clinical feature with discriminant value is sausage digit or dactylitis seen in reactive arthritis or psoriatic arthropathy. Herein, the entire digit is diffusely swollen. This is clinically a very important point of distinction from joint diseases like RA where only the joint gets swollen (fusiform or spindle-shaped swelling) and not the entire digit (**Figures 2A and B**).

The term polyarthritis refers to involvement of more than four joints. It may be due to inflammatory causes like RA, SLE, psoriasis, systemic sclerosis (SSc), juvenile idiopathic arthritis (JIA), rheumatic fever (RF), adult-onset Still's disease, etc. or non-inflammatory causes like OA. Hand examination is crucial in patients with polyarthritis as explained below.

Symmetry

Symmetrical involvement refers to affliction of the same joints on right and left sides. Even in symmetrical involvement, mirror image symmetry is not required. To clarify things, involvement of right 4th, 5th and left 2nd metacarpophalangeal (MCP) joints is deemed symmetrical involvement of MCP joints. RA, systemic lupus erythematosus (SLE), SSc, and nodular OA of hands are typical examples of symmetric polyarthritis. Gout and SpA are typically asymmetric oligoarthritides. Psoriasis can cause either asymmetric oligoarthritis or symmetric polyarthritis. The most important practical point is that a clinician should hesitate to give a diagnosis of RA, if the disease is asymmetrical.

UPPER LIMB VERSUS LOWER LIMB JOINT INVOLVEMENT

This can provide a clue to the differential diagnosis. Joints of both upper and lower limbs are involved in RA, SLE and psoriasis. Predominant involvement of lower limbs is seen in gout, SpA and erythema nodosum, whereas, haemochromatosis preferentially affects joints of upper limbs.

Type of Joints Affected

Small versus large

RA typically affects both small and large joints. In fact, inflammatory, symmetric polyarthritis of small joints of hands like MCP joints and proximal interphalangeal (PIP) joints, is a characteristic feature of RA. Similarly, psoriasis, lupus and SSc affect both small and large joints. In contrast, SpA affects large joints much more than smaller joints. Therefore, the typical pattern of joint involvement in SpA is asymmetric oligoarthritis of large joints of lower limbs. Thus, the pattern in RA and SpA is quite different and distinctive, permitting bedside recognition.

Specific joints

These can give a clue to the nature of arthritic illness, e.g. distal interphalangeal (DIP) joint involvement is characteristic of OA, while DIP joints are spared in RA. Other conditions which give rise to DIP joint involvement are psoriasis and SSc. Involvement

Figures 2A and B: (A) Dactylitis seen in reactive arthritis versus (B) fusiform swelling in rheumatoid arthritis.

of the first carpometacarpal joint is typical of OA, while ankle and shoulder are rarely involved in primary OA.

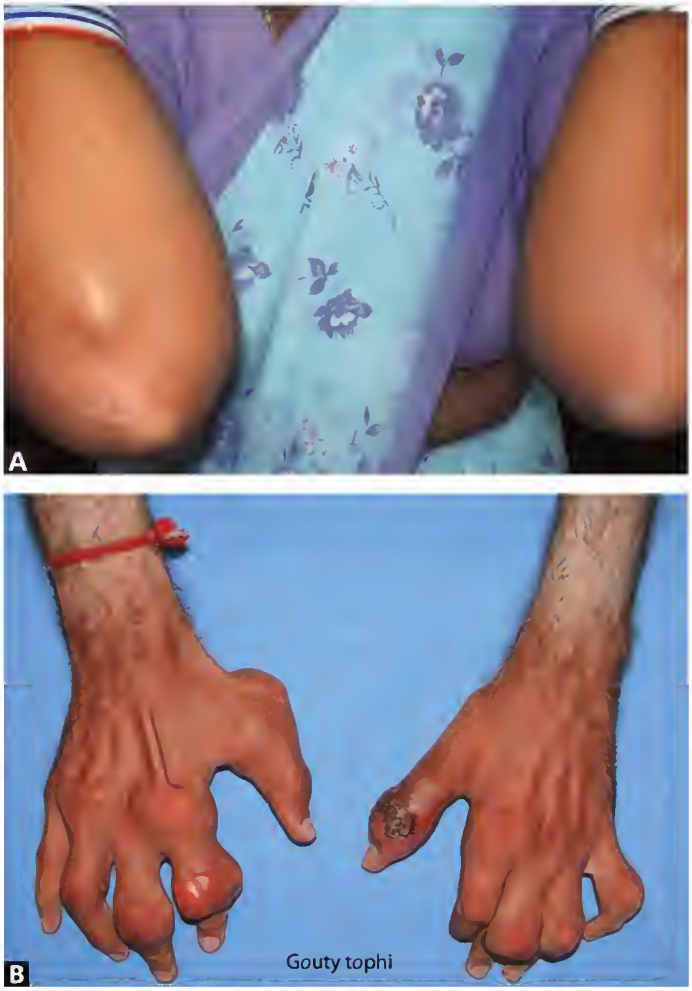
Spine

Spinal involvement other than cervical spine is rare in RA. In contrast, inflammatory low back pain is a characteristic feature of SpA.

Sequence or Pattern of Involvement

The three common patterns of joint involvement are intermittent, additive, and migratory. Intermittent arthritis is episodic and the patient may be totally asymptomatic in between the episodes. Examples include gout, Behçet's syndrome, Reiter's syndrome, intermittent hydrarthrosis, and palindromic rheumatism. Additive arthritis is one where more and more joints are afflicted with time. This is seen with RA, SpA, psoriasis, OA, etc. Migratory polyarthritis refers to a pattern wherein pain and swelling in a specific joint starts rapidly and subsides in 24 to 36 hours; the arthritis then picks up new joints. The difference from additive pattern is that the previously involved joints in migratory pattern return to normal as new joints become involved, whereas in the former the joint involvement persists. Migratory pattern is seen in rheumatic fever, gonococcal arthritis, viral disease, sarcoidosis, and bacterial endocarditis.

These patterns may not be seen in the classical form due to treatment received by the patient. Also, these patterns may coexist in the same patient. However, when one pattern dominates, it may suggest a particular diagnosis.



One of the commonly overlooked diagnoses in India is juvenile idiopathic arthritis (JIA), formerly known as juvenile rheumatoid arthritis (JRA) or juvenile chronic arthritis (JCA), in children below the age of 16 years. There is a tendency to label all joint pains in children as rheumatic fever (RF) with undue reliance on one laboratory marker, that is, elevated ASO (anti-streptolysin O) titres. The joint pains in RF are migratory, affect large joints and tend to subside over 6-12 weeks, with or without treatment. The major brunt is borne by the heart. In contrast, the arthritis in JIA tends to be additive, persistent, and may involve small or large joints. The presence of deformities strongly militates against a diagnosis of RF, since the arthritis in RF is most often non-deforming.

Extra-Articular Features

Features that may be associated with joint involvement like fever, skin lesions, nodules, etc. play a role in differential diagnosis. Fever along with arthritis narrows down the diagnostic possibilities to SLE, systemic-onset JIA (Still's disease), vasculitis, infective endocarditis, rheumatic fever and adult-onset Still's disease. It is important to realise that although malaise is very common in RA, fever of moderate-to-high grade is not seen with RA and should necessitate a search for other causes.

Mucosal or cutaneous lesions are seen in SLE, psoriasis, Behçet's syndrome, reactive arthritis, SSc, erythema nodosum, vasculitides, gonococcal arthritis, etc. The malar rash of SLE is characteristic and can be appreciated even in dark skinned individuals. Gonococcal infection usually occurs in young, sexually active adults and the skin lesions comprise of a pustule with an erythematous base. Nail changes of psoriasis can easily be masked by nail paint in female patients.

The type of eye involvement may also vary with different eye diseases. RA usually causes keratitis or scleritis in contrast to uveitis seen in SpA. A detailed description of skin/eye manifestations of various rheumatic diseases is beyond the scope of this chapter.

Figures 3A and B: Arthritis with nodules.

Conditions causing nodules in a patient with arthritis include RA, OA (Heberden and Bouchard nodes), tophaceous gout, rheumatic fever, multicentric reticulohistiocytosis, sarcoidosis, erythema nodosum, vasculitides, etc. (**Figures 3A and B**). However, the associated features make the pattern recognition possible. For example, carditis, migratory polyarthritis, erythema marginatum and chorea in RF hold the clue to diagnosis. Rheumatoid nodules are uncommon in Indian patients with RA when compared to Western patients. Similarly, nodular OA of hands is less often encountered in India as compared to Caucasians.

CONCLUSION

Rheumatology is predominantly a clinical subspecialty. Pattern recognition, based on detailed history and thorough physical examination, remains the cornerstone of the diagnostic approach to a patient with musculoskeletal complaints. A good history provides as much as 80% of diagnostic information, with the physical examination and investigations contributing only 15% and 5%, respectively.

24.2 Soft Tissue Rheumatism and Regional Rheumatic Pain Syndromes

Ved Chaturvedi

INTRODUCTION

Soft tissue rheumatism refers to symptoms arising not from the joints themselves, but those that arise from the periarticular structures, such as ligaments, tendons, insertion of tendons at bony sites (entheses), tendon sheaths, bursae and muscles. STR may present clinically in two main forms:

1. Localised (regional) pain syndromes
2. Diffuse pain syndrome or fibromyalgia

Regional rheumatic pain syndromes are a common presentation in general practice. Diagnosis of these pain syndromes is predominantly clinical and depends upon general awareness of these disorders and knowledge of anatomy, especially soft tissue structures. One important point which the author has learnt is to use two colour pens for marking the exact site of pain—red for swelling and blue for pain. The author terms this method as 'Red Blue Marking Method' for regional rheumatic pain syndromes which leads to better symptom localisation. It is more rewarding to do a thorough physical examination and use the simple marking methods than ordering unnecessary tests. The aetiopathogenesis of regional rheumatic pain syndromes is still unclear. Factors implicated include genetic, environmental, occupational, repetitive trauma, psychological, etc. The regional rheumatic pain syndromes are classified by the major anatomical structure involved (**Table 1**). Low backache has been dealt within a separate chapter.

Table 1: Common Regional Rheumatic Pain Syndromes

Shoulder
- Rotator-cuff disorders
- Bicipital tendinitis
- Adhesive capsulitis (frozen shoulder)

Elbow region
- Olecranon bursitis
- Lateral epicondylitis (tennis elbow)
- Medial epicondylitis (golfer's elbow)

Wrist
- DeQuervain's tenosynovitis
- Carpal-tunnel syndrome
- Trigger finger/thumb
- Dupuytren's contracture

Hip
- Trochanteric bursitis
- Iliopsoas bursitis
- Ischial bursitis
- Meralgia paraesthetica

Knee
- Bursitis (pre; infra-patellar, anserine)
- Baker's cyst
- Osteochondritis dissecans
- Traction apophysitis
- Anterior knee pain syndrome
- Patellar instability syndrome

Ankle and foot
- Achilles tendinitis
- Retrocalcaneal bursitis
- Plantar fasciitis
- Bony deformities
- Morton's neuroma
- Metatarsalgia

DISORDERS OF THE SHOULDER REGION

Shoulder pain may have its origin in the glenohumeral joint, acromioclavicular joint or periarticular structures, or be referred from the cervical spine (felt at the supraspinatus region), thoracic outlet, subdiaphragmatic conditions (felt at the tip of the shoulder), or brachial plexus. Rotator cuff disorders (impingement syndrome) are the most common cause of shoulder pain. The spectrum ranges from mild tendinitis of the rotator cuff, with or without inflammation of the adjacent subacromial bursa, to bicipital tendinitis, tears of the rotator cuff and secondary glenohumeral osteoarthritis. Trauma, unaccustomed activities, ageing, vascular compromise, etc. are contributory factors.

Rotator Cuff Disorders

The presentation of rotator-cuff lesions depends on the age of the patient. Young adults often present acutely after forceful activity like throwing or after trauma. In the middle-aged individuals, the onset is more gradual and history of repetitive or strenuous upper limb activity may be present. There may be no precipitating factors in the elderly patients. The patient typically experiences pain on active abduction, and sometimes when lowering the arm. Patients have difficulty in working overhead or lifting and reaching behind their back when dressing. Clinical examination reveals limitation of active movement by pain, and tenderness localised to the rotator cuff and greater tuberosity. The 'supraspinatus' or 'empty can' sign (pain on resisted elevation of the arm to 90° midway between abduction and forward flexion with the thumb pointing downwards in internal rotation) is often positive. Neer's 'impingement sign' (one hand of the examiner forward flexing the patient's arm while the other hand restricting scapular rotation) is positive; the patient develops pain in the overhead position near the end of full flexion. Rotator cuff tears can be partial or complete. Clinical features include shoulder pain on abduction, night pain, varying degrees of weakness of abduction and external rotation, local tenderness and loss of range of movement. The supraspinatus and impingement signs are usually positive: inability to actively maintain 90° of passive shoulder abduction. Magnetic resonance imaging and ultrasound are employed for diagnostic imaging.

Initial management of rotator cuff tendinitis consists of rest, nonsteroidal anti-inflammatory drugs (NSAIDs), and physical treatments including heat application and range of movement exercises (early mobilisation of the shoulder is important in minimising the disability). If symptoms persist for more than 2 to 4 weeks, injection of a depot corticosteroid into the nearby subacromial bursa is often beneficial. Surgery is indicated for intractable pain and severe functional impairment.

Bicipital Tendinitis

Bicipital tendinitis is often related to chronic impingement of the bicipital tendon by the acromion. It usually occurs in association with rotator cuff tendinitis and glenohumeral instability. The pain is felt over the anterior aspect of the shoulder after radiating into the biceps muscles. It is increased by the overhead activities, shoulder extension and elbow flexion. Localised tenderness is present over the tendon in the

bicipital groove. Bicipital tendon pain can be reproduced by resisted supination of the pronated forearm with the elbow 90° flexed, shoulder flexion against resistance. Treatment entails rest, NSAIDs, and physical modalities like hot packs, ultrasound, etc. Some cases require local corticosteroid injection into the tendon sheath parallel to the tendon fibres. Care should be taken to avoid direct injection into the tendon.

Subacromial Bursitis

Chronic subacromial bursitis often occurs in association with rotator cuff tendinitis and chronic impingement. Primary subacromial bursitis due to trauma, infection, rheumatoid arthritis (RA), or other arthritic disorders is rare. Abduction is painful, and there is local tenderness and sometimes fluid distension of the bursa, which is visible just anterior to the acromion with the shoulder extended.

Adhesive Capsulitis

Adhesive capsulitis, also known as frozen shoulder capsulitis, or pericapsulitis, is characterised by progressive, global restriction of shoulder movements associated with pain and functional disability. A period of immobility of the shoulder is the most commonly identified predisposing factor. It is more common after the sixth decade and in females. The condition may also coexist with diabetes mellitus, hypothyroidism, lung carcinoma, myocardial infarction, cardiac surgery and shoulder trauma. Although adhesive capsulitis is often a self-limiting disorder, the extent and rate of recovery are variable. Dynamic sonography, demonstrating limitation of sliding movements of the supraspinatus tendon during abduction of the arm is diagnostic. Treatment of adhesive capsulitis consists of NSAIDs, physical therapy and corticosteroid injections into both the glenohumeral joint and subacromial bursa. Physiotherapy is important. Gentle range of movement exercises, beginning with pendulum exercises and wall climbing with the fingers, and finally active strengthening exercises, are required to restore joint mobility. Operative capsulotomy, with surgical release of the coracohumeral ligament and of subacromial adhesions, is occasionally beneficial in patients with chronic symptoms refractory to conservative treatment.

DISORDERS OF THE ELBOW REGION

Lateral epicondylitis (tennis elbow), medial epicondylitis (golfer's elbow), and olecranon bursitis are the common soft tissue lesions at the elbow.

Lateral Epicondylitis (Tennis Elbow)

It usually afflicts the dominant arm in individuals aged 40 to 60 years. In actual practice less than 5% cases can be attributed to tennis playing. There are no specific precipitating factors for this condition, which results from inflammation of the soft tissues attaching to the lateral epicondyle, especially, extensor carpi radialis brevis tendon. Patients present with pain over the lateral epicondyle and the surrounding area. Grip may be impaired and routine activities like lifting weight, shaking hands may produce pain. Examination reveals tenderness over the lateral epicondyle. Another cardinal sign is increase in pain in resisting wrist dorsiflexion while the elbow is in extension. Symptoms may also be precipitated by extending the elbow with wrist palmar flexed. Physical modalities like heat or cold, NSAIDs and local corticosteroid injections are used for its management. Some patients benefit by elbow splinting also. Refractory cases may need surgical intervention in the form of lateral release of the extensor tendon.

Medial Epicondylitis (Golfer's Elbow)

This is much less common than tennis elbow and results from involvement of the common flexor tendons at the medial epicondyle. Pain over the medial side of elbow on resisted wrist flexion while the elbow is extended in a reliable sign. The management is similar to that of lateral epicondylitis.

Olecranon Bursitis

The subcutaneous olecranon bursa is a frequent site for traumatic, inflammatory, and septic bursitis. Inflammatory olecranon bursitis may be due to RA, psoriatic arthritis, gout or sepsis. Non-septic olecranon bursitis can result from repetitive, minor, or unnoticed trauma to the elbow. It is less disabling as pain is minimal. Local tenderness and swelling are present. Management involves aspiration, NSAIDs, and one or more injections of corticosteroid.

DISORDERS OF THE WRIST AND HAND

DeQuervain's Tenosynovitis

DeQuervain's tenosynovitis of the abductor pollicis longus and extensor pollicis brevis is commonly due to repetitive occupational activity. It is common in females in the age group of 30 to 50 years. It may also occur in association with RA, psoriatic arthritis, and pregnancy, and during the post-partum period. Most patients complain of pain along the radial aspect of the wrist and at thumb base during pinch grip, grasping and other hand activities. Finklstein's test is positive (the thumb is flexed into the palm and wrist deviated ulnarly resulting in pain over the radial side). Treatment consists of heat application, NSAIDs, and splinting.

Trigger Finger or Thumb (Stenosing Digital Tenosynovitis)

The pathological lesion is tenosynovitis of the flexor tendons of the finger or thumb, resulting in fibrosis localised to the annular pulley that overlies the metacarpophalangeal joint. A nodular thickening of the tendon often develops at the site of stenosis, that interferes with the normal gliding of the tendon, resulting in pain over the area of the pulley and 'snapping' or 'triggering' of the finger or thumb. Examination reveals tenderness over the area of the proximal pulley, and often limitation of digital flexion and extension. Management consists of heat application, exercises, NSAIDs and local steroid injections.

Dupuytren's Contracture

This presents as nodular thickening and contraction of the palmar fascia which may lead to flexion contractures of the fingers. The ulnar side is commonly affected. Treatment involves physiotherapy and local steroid injections.

DISORDERS OF THE HIP REGION

It is important to differentiate pain arising from hip joints and adjacent structures from referred pain. Referred pain at the hip can be due to thoracolumbar spine disorders, peripheral vascular diseases and intra-abdominal pathology. The skin over the greater trochanter is innervated by T12 roots, while L1 supply the inguinal region and L2-4 supply the anterior aspect of thigh. Radiculopathies due to spine disorders can, therefore,

mimic hip pain. However, in these illnesses there is no limitation of hip movements. Abdominal problems like inguinal or femoral hernias, ureteric stones, tuberculous abscess, retroperitoneal appendicitis and pelvic inflammatory diseases may also masquerade as hip arthritis. Careful clinical examination makes differentiation possible at the bedside. Thrombosis or aneurysm of aorta and its iliac branches can give rise to buttock, thigh or calf pain that may be confused with hip pain. Examination of peripheral pulses can be rewarding in such a situation. The common rheumatic pain syndromes around the hip include trochanteric bursitis, ischiogluteal bursitis and illopsoas bursitis.

Trochanteric Bursitis

Patients with trochanteric bursitis present with a deep, aching pain over the lateral upper thigh which is often intensified by walking but it may be worse at night, especially when the patient is lying on the affected side. The diagnosis is confirmed with palpation of the posterior aspect of the greater trochanter which elicits local tenderness in this area. Treatment includes rest and local injection of depot steroids.

Ischiogluteal Bursitis

Also called 'weaver's bottom', it results from prolonged sitting on hard surface. The bursa lies over the ischeal tuberosity and helps gliding of the gluteus maximus muscle. The diagnosis is made by the characteristic history and by eliciting tenderness on palpation of the ischeal tuberosity with the patient lying supine with the hip flexed. Treatment consists of using a cushioning seat, NSAIDs, stretching exercises while lying on the cushion. A local depot steroid should be given cautiously due to adjoining sciatic nerve.

Iliopsoas Bursitis

The bursa lies over the anterior surface of the hip joint under the iliopsoas muscle and between the hip joint capsule. Typically, patients present with an inguinal mass which may be painful and may be associated with secondary femoral vein obstruction or femoral nerve compression. Intra-articular pathology of hip joint may be associated with the bursitis.

DISORDERS OF THE KNEE REGION

Knee pain is a common articular complaint. Non-arthritic conditions comprise a large proportion of knee complaints, particularly in younger age groups.

Pre-Patellar Bursitis

Pre-patellar bursitis presents as a painful, red swelling anterior to the kneecap and is seen most often in people who spend a lot of time kneeling. Active knee extension is usually quite painful although passive knee flexion is usually only minimally limited. Infection, gout and repeated trauma are usual factors.

Infra-Patellar Bursitis

The deep infra-patellar bursa lies between the upper portion of the tibial tuberosity and patellar ligament and it is separated from the knee joint synovium by a fat pad. It presents as tenderness in the soft tissues of either side of the ligament just proximal to its insertion on the tibial tubercle.

Anserine Bursitis

The anserine bursa is located about 5 cm below the medial aspect of the knee. Anserine bursitis is a term loosely applied to pain and associated local tenderness in this region. The typical presentation is that of an obese woman presenting with nocturnal pain, and rarely, a palpable mass on upper and medial aspect of tibia.

Gastrocnemius-Semimembranous Bursitis (Baker's Cyst)

Any cause of synovitis in the knee can lead to leakage into the popliteal space when a communication exists between the gastrocnemius-semimembranous bursa. Symptoms consist of fullness and tightness in the popliteal space which increases with walking. A Baker's cyst can be detected clinically by palpation of fullness in the medial-third of the popliteal fossa. Ultrasonography will establish the diagnosis in most of the cases (**Figure 1**). Baker's cysts may dissect into the muscles of the calf, simulating thrombophlebitis. Rupture of a Baker's cyst should be confirmed by Doppler ultrasound.

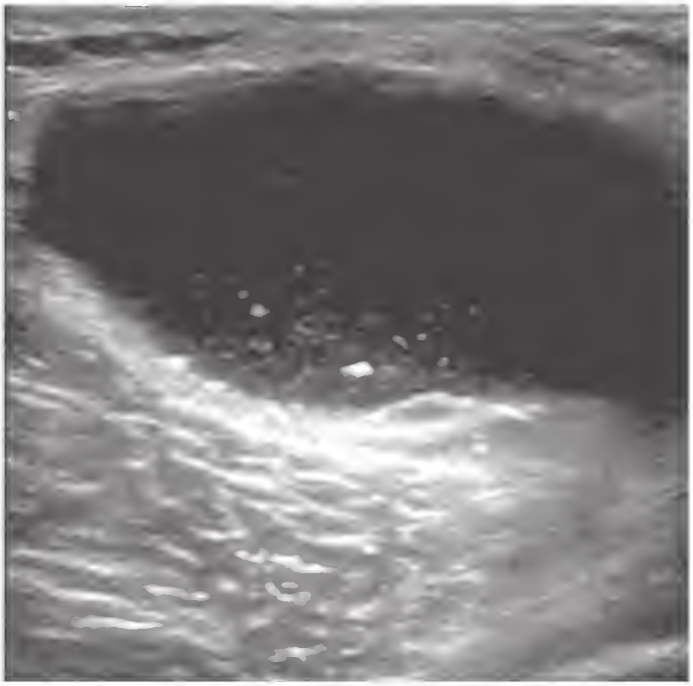

Figure 1: Ultrasound demonstrating Baker's cyst.

Treatment of an intact or ruptured Baker's cyst includes depot steroid injection in knee. Due to close proximity of popliteal vessels, it is wise not to use posterior approach for direct aspiration of the Baker's cyst.

Iliotibial Band Syndrome (Runner's Knee)

The iliotibial band is a fascial band connecting the ilium with the lateral tibia, connecting to the tensor fasciae lata and the gluteus maximus. Repetitive flexion and extension, particularly with high intensity running, can lead to inflammation of the iliotibial band or at its associated bursa overlying the lateral femoral condyle. Examination reveals tenderness localised to the lateral femoral condyle approximately 2 cm above the joint line, pain with weight bearing on the knee when flexed 30° to 40°. Treatment consists of rest, local heat, and depot corticosteroid.

Internal Derangements of Knee

Internal derangements of the knee refer to disruption of the normal functioning of the ligaments and menisci usually due to significant, often athletic trauma. MRI and arthroscopy are helpful in diagnosis.

Patellofemoral Pain Syndrome

Chondromalacia patellae is a term which has been used synonymously with patellofemoral pain. It is most commonly described as poorly localised, anterior knee pain, frequently accompanied by the 'grab' sign (patients cover the entire front of the knee with the band when asked to identify the location of the discomfort). Pain frequently occurs after prolonged sitting with flexed knees, the so-called 'theatre' sign. Treatment modalities include avoidance of overuse, exercises, and anti-inflammatory medications.

DISORDERS OF THE FOOT

The most common causes of heel pain are Achilles tendinitis, retrocalcaneal bursitis, and plantar fasciitis. Achilles tendinitis presents with gradual onset of pain with foot push off. Physical examination reveals tenderness and occasionally thickening of the tendon which can also be detected by ultrasonography (**Figure 2**). Retrocalcaneal bursitis is associated with posterior heel pain and may be associated with tender swelling on both sides of the insertion of the tendon. Localised pain with weight-bearing on the undersurface of the heel is the typical presentation. Spondyloarthopathy, trauma, gout and hypothyroidism are the few known causes. Treatment consists of a heel pad or cushion, rest, local heat, anti-inflammatory agents or in some cases local steroid injection. Plantar fasciitis is the most common cause of subcalcaneal heel pain. Patients usually complain of pain on the undersurface of heel on weight bearing, especially after a period of rest, e.g. on taking the first few steps on awakening in the morning. Localised tenderness may be elicited on the anteromedial part on calcaneum on its plantar surface. Radiographs are often normal. Plantar spurs, if seen, are often not the cause of the heel pain which is due to inflammation of the plantar fascia. Causes include repetitive overuse as in athletes, excessive standing and walking, improper footwear with hard soles, and spondyloarthropathies. Treatment is by means of rest, hot fomentation, NSAIDs, soft footwear with heel cushions, ultrasound therapy, and sometimes local injection of corticosteroids.

Metatarsalgia

Metatarsalgia is the symptom of pain across the plantar surface of one or more metatarsophalangeal joints and may be due to diverse causes including callosities, flat-foot, arthritis, muscle imbalance, fat pad atrophy, Morton's neuroma, hallux valgus or rigidus, tarsal tunnel syndrome, and arterial insufficiency. Tarsal tunnel syndrome most often refers to compression of the posterior tibial nerve as it courses around the medial malleolus. The typical presentation is with dysaesthesias involving the plantar aspect of the foot that is often more prominent at night. The diagnosis of tarsal tunnel syndrome may be confirmed by nerve conduction studies documenting delay in conduction of the posterior tibial nerve across the ankle.

DIFFUSE PAIN SYNDROME AND FIBROMYALGIA

Fibromyalgia is a clinical syndrome characterised by persistent, diffuse pain in the body. This is typically described by the patient as "pain all over the body" including joints, muscles and spine. However, there is no clinical discernible evidence of inflammation at any of these sites, and therefore, this condition is classified as soft tissue rheumatism. This is more commonly seen in young or middle-aged women and the pain is accompanied by a number of other symptoms including: fatigue, depressed mood, sleep disturbance, headaches and social isolation. Clinical examination reveals multiple, soft tissue tender points over bony prominences, muscles and tendons. The American College of Rheumatology (ACR) classification criteria in vogue required tenderness on pressure (tender points) in at least 11 of 18 specified sites and the presence of widespread pain for diagnosis. Widespread pain was defined

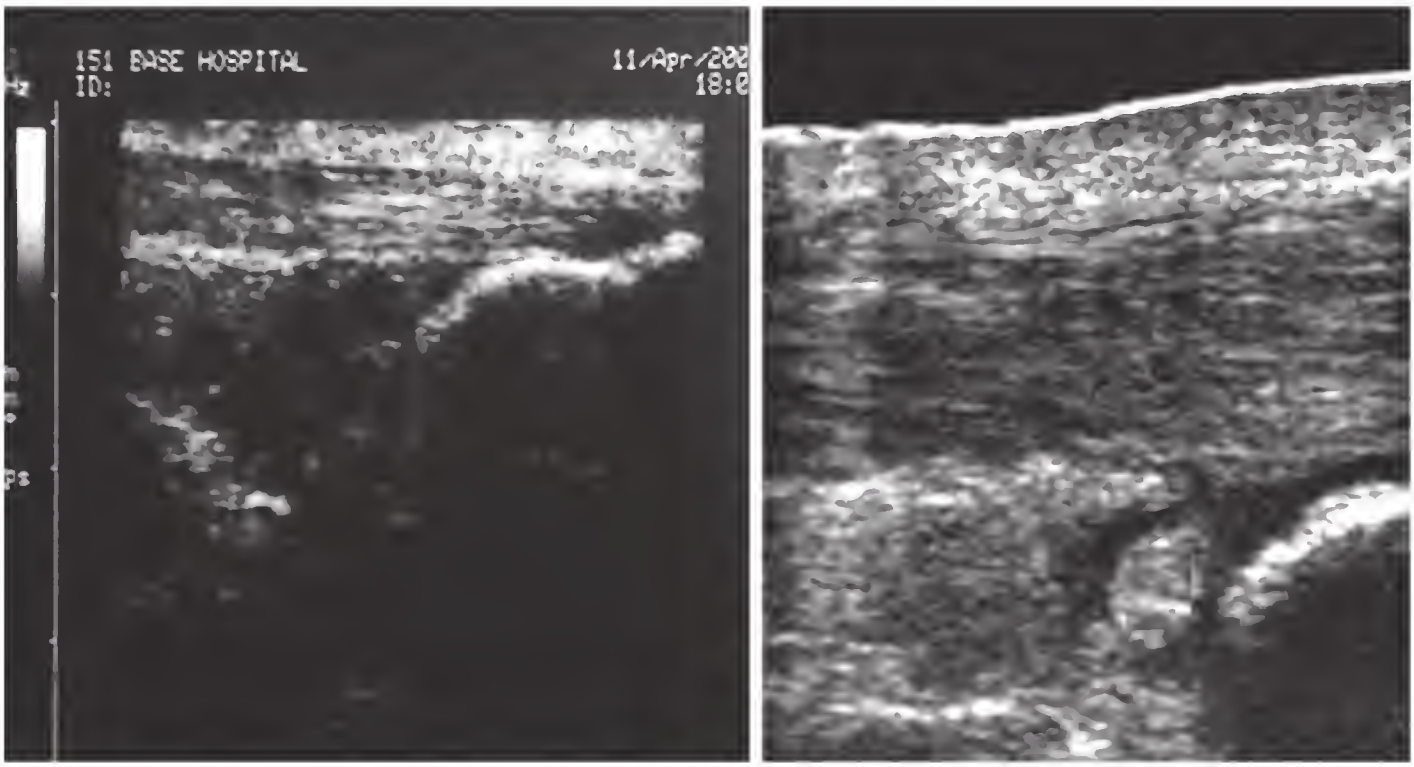

Figure 2: Ultrasound demonstrating Achilles tendinitis.

as axial pain, left- and right-sided pain, and upper and lower segment pain. Recently, the American College of Rheumatology has proposed diagnostic criteria for fibromyalgia that do away with tender point examination and permit a symptom-based diagnosis. A patient satisfies diagnostic criteria for fibromyalgia if the following three conditions are met:

1. Widespread pain index (WPI) >7 and symptom severity (SS) scale score >5 or WPI 3-6 and SS scale score >9.
2. Symptoms have been present at a similar level for at least 3 months.
3. The patient does not have a disorder that would otherwise explain the pain.

The WPI score ranges from 0 to 19 while the SS score ranges from 0 to 12. The successful management of fibromyalgia requires both non-pharmacological and pharmacological measures, with particular emphasis on patient education, in order to explain the nature of the disease and to highlight that joint or bone damage will not occur in this condition, unlike untreated inflammatory arthritis. A suitable programme of graded exercises can be very helpful in maintaining adequate mobility and improving functional capacity. Psycho-behavioural management can also help and these include psychotherapy, hypnotherapy and relaxation response therapy, where available. The drugs that might be useful are analgesics and NSAIDs, tricyclic anti-depressants such as amitryptyline, fluoxetine, gabapentin and pregabalin. For one or two very troublesome tender points not responsive to analgesics or NSAIDs, a local steroid injection may often be helpful.

CONCLUSION

Regional rheumatic pain syndromes, despite being very common in clinical practice, are neither properly recognised nor adequately treated. There are usually no serologic markers or pathognomonic imaging findings. Awareness of the entity and a basic knowledge of regional rheumatic anatomy are sufficient to permit clinical recognition in the vast majority of the cases. Treatment is simple and comprises patient education, NSAIDs, physical modalities like heat, cold, ultrasound therapy, etc. and intralesional corticosteroids.

24.3 Low Backache

C Panchapakesa Rajendran, S Rajeswari

INTRODUCTION

Low back pain (LBP) is the most common rheumatic disorder accounting for 30% to 50% of rheumatic musculoskeletal complaints encountered by general practitioners. As an ailment, it is second only to the common cold with 70% to 80% of the population experiencing LBP at some point of time. Most often it is a self-limited illness and becomes chronic only in 5% of cases. LBP is the most common pain syndrome in industrial countries with the highest prevalence in persons aged 45 to 65 years. The incidence in the industrial sector in India is 11% in textile workers.

ANATOMICAL CONSIDERATIONS

The functional unit of the lumbar spine consists of two vertebral bodies and an intervertebral disc anteriorly and the facet joints posteriorly (**Figures 1 and 2**). The anterior portion is flexible and serves the functions of shock absorbency and weightbearing. The nucleus pulposus provides shock absorbency to the disc and the annulus fibrosus allows for the flexibility of the functional unit. The posterior portion of the unit protects the neural elements. It acts as a fulcrum and guides the movements for the functional unit. The lower lumbar discs need to bear a load of 1000 kg when stressed with pure compression forces. The posterior segment muscles and abdominal muscles help to dissipate these compression loads. The sacrum and iliac bones function as one unit. The lumbosacral angle also plays a role in determining the posture and degree of spinal curvature. The back is sensitive to 4 to 8 Hz vibrations and whole body vibration produce buckling and slipping of the lumbar discs and degeneration.

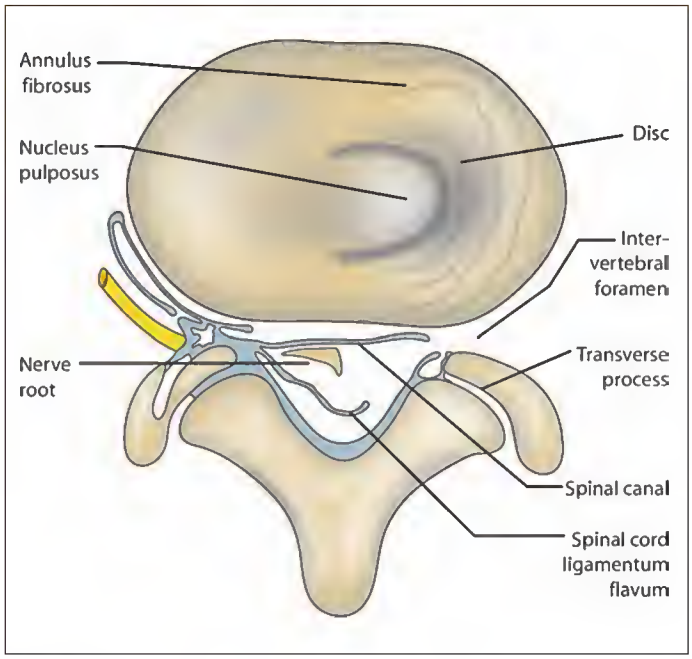

Figure 1: Normal lumbar spinal canal.

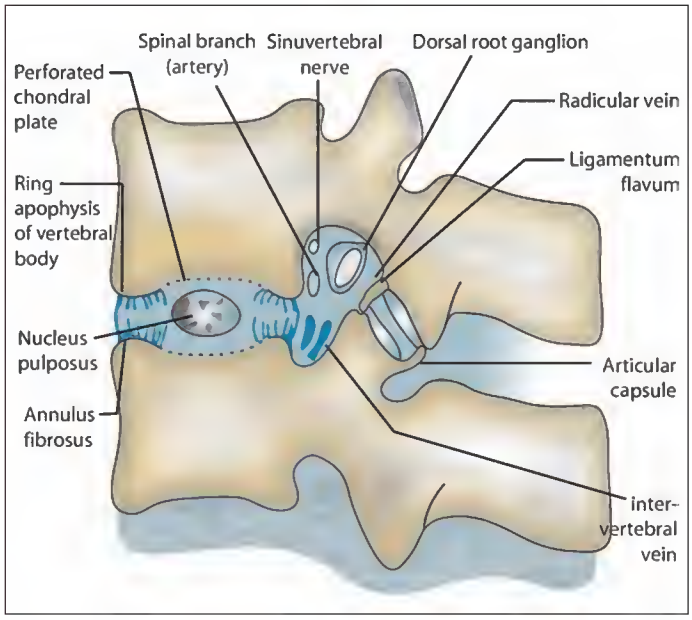

Figure 2: Sagittal section of spine.

AETIOLOGY

Aetiologies of low backache are enumerated in **Table 1**.

Clinical Features and Approach

A detailed history of involved relevant systems, a good social history, and methodical clinical examination are essential for arriving at a diagnosis. LBP can present as acute or chronic pain (**Table 2**). Acute LBP is one where the duration is less than 1 month, subacute from 1 to 3 months, and chronic if the duration is more than 3 months or if pain occurs episodically within a 6 months period. Mechanical causes of low backache account for the majority (90%) of cases while systemic diseases account for only 10%. Acute LBP has a favourable natural history. Most episodes resolve in a few weeks. In one-third of patients, the LBP may last for a month. Chronic LBP of more than 3 months duration is seen only in a minority.

Acute Low Back Pain

It is important to rule out catastrophic conditions enumerated in **Table 3** as they require emergency intervention.

Certain 'Red Flags' (danger signs) of serious disease should be looked out for when dealing with acute LBP. These include history of trauma, fever, incontinence, unexplained weight loss, cancer, long-term steroid use, parenteral drug abuse, intense local pain, human immunodeficiency virus infection, thoracic pain, neurological symptoms, structural spinal deformity, inability to get into a comfortable position associated with a pattern of symptoms not compatible with benign mechanical disease, and lack of response to conservative measures.

'Yellow Flags' are signs which identify patients at risk for chronicity and disability. These include factors like age, physical

fitness, abdominal muscle weakness, smoking, obesity, low educational level, high pain levels and disability, etc. psychosocial factors (like poor cognitive functioning, anxiety, stress, depression, distress, somatisation, etc.), and occupational factors (like manual material handling, bending and twisting, whole body vibration, poor work relationships, social support and job dissatisfaction).

Table 1: Aetiologies of Low Backache

Congenital
- Abnormal vertebral facets
- Sacralisation of L5 transverse process
- Spondylolysis or spondylolisthesis between L5 and S1 vertebrae (Figure 4)

Acquired Inflammatory
- Infective
  - Osteomyelitis, e.g. tuberculosis
  - Discitis
  - Epidural abscess
- Non-infective or rheumatologic
  - Spondyloarthropathies (e.g. ankylosing spondylitis)
  - Trauma to ligaments, muscles, vertebrae or annulus fibrosus with disc prolapse

Vascular
- Abdominal aortic aneurysm dissection
- Epidural haematoma
- Haemoglobinopathies

Neoplastic
- Primary tumours of the spine, e.g. multiple myeloma
- Metastatic

Degenerative
- Disc disease
- Facetal arthropathy
- Spinal canal stenosis

Metabolic
- Osteoporotic vertebral fracture
- Paget's disease

Mechanical
- Poor posture aggravated by
  - Obesity
  - Pregnancy
  - Over work

Referred Pain
- Abdominal viscera (renal, pancreas, posterior duodenal ulcer)
- Pelvic disorders (pelvic inflammatory disease)

Soft Tissue Rheumatism
- Fibromyalgia
- Psychogenic/Malingering
- Miscellaneous
- Whole body vibration
- Computer-related

Chronic Low Back Pain

Patients belonging to this category are those who have not responded to six weeks of conservative management. These patients can be divided into four groups based on the location and radiation of pain as described below:

Localised low back pain

Pain not radiating below the gluteal region forms the largest group in which inflammation, infections, tumour and degeneration have to be ruled out.

Sciatica

Pain radiating below the knee and down the leg and associated with mechanical impingement upon the nerve. A positive straight leg raising test (Figure 3) indicates a herniated intervertebral disc while a positive exercise stress test is in favour of lumbar canal stenosis.

Anterior thigh pain

Conditions like inguinal hernia, hip joint disease, diabetic mononeuropathy, renal calculi, abdominal aneurysm and retroperitoneal tumours have to be ruled out with appropriate investigations.

Posterior thigh pain

It may be due to back strain and referred pain due to damage of muscles in the lumbosacral spine or a high herniated disc (L3-L4 level). Clinical tests to distinguish inflammatory from mechanical back pain should be done (Table 4).

Some special situations are summarised in Table 5.

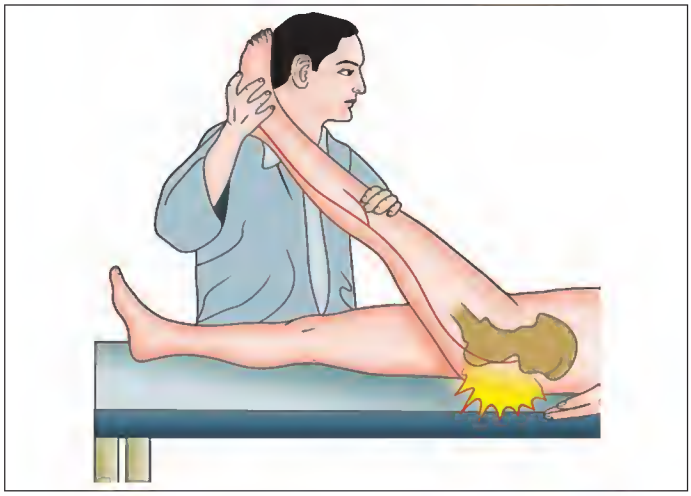

Figure 3: Straight leg raising test. The leg is raised 30° to 70° until radicular symptoms are elicited, when test is positive.

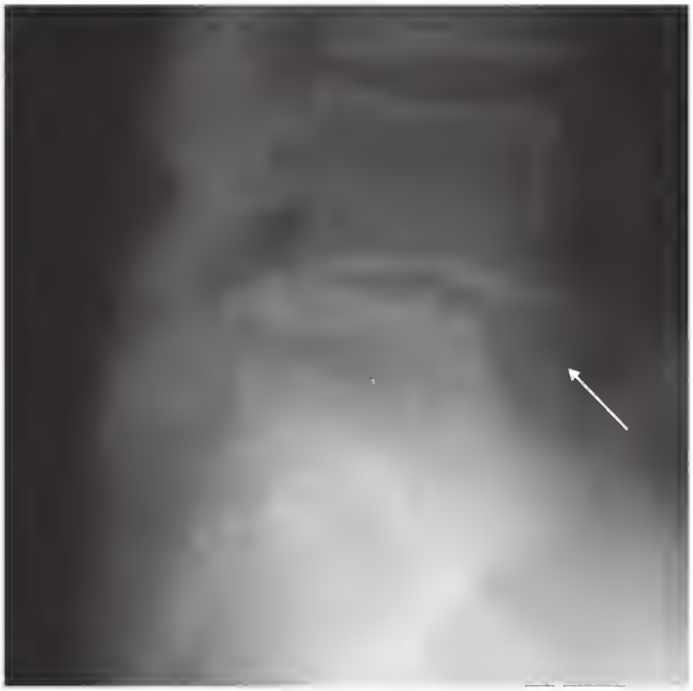

Figure 4: Spondylolisthesis at L5 level.

Table 2: Classification and Features of Low Back Pain

Category	Pathologic Entity	Quality	Location	Onset and Duration	Aggrevating Alleviating Factors	Neurologic Deficit
Superficial somatic (skin, subcutaneous tissue)	Cellulitis	Sharp	Well localised	Acute	Intensified by direct contact	None
Deep somatic	Muscular strain	Sharp	Diffuse	Acute or chronic	Intensified with movement	None
	Arthritis Fracture	Dull Boring	Multiple segments	Chronic	Diminished with rest	None
Radicular	Discogenic	Segmental	Low back	Acute	Aggravated by bending, sitting, Valsalva manoeuvre	None
	Spinal stenosis	Radiating, claudication, paraesthesia	Afferent distribution of affected nerve root	Acute/chronic	Aggravated by lumbar extension, walking, standing relieved by flexion, sitting	Present
Visceral referred	Pancreas, intestine, prostate, endometriosis, abdominal aneurysm	Deep, colicky, boring, tearing	Segmental with radiation inside body	Acute/chronic	Not affected by motion, walking, etc.	None
Nerve root pain	Diabetic femoral neuropathy	Burning paraesthesia, numbness	Radicular		Intensified by sensory stimulation of the damaged nerve	Present
Psychogenic	Depression, conversion reaction, malingering	Variable	Non-dermatomal	Persistent	No consistent correlation	None

Table 3: Catastrophic Conditions Leading to Acute Low Back Pain

Leaking or ruptured abdominal aneurysm
Acute paraplegia due to central herniation of nucleus pulposus presenting as cauda equina syndrome
Epidural haemorrhage
Embolus
Anterior spinal artery thrombosis
Epidural abscess
Spinal cord tumours

Table 4: Differences between Pain due to Inflammatory and Mechanical Causes

Feature	Inflammatory	Mechanical
Age of onset	20-40 years	Any age
Sex	Male > female	Equal
Onset	Subacute	Often acute
Effect of activity	Relieves	Aggravates
Effect of rest	Aggravates	Improves
Radiation to legs	+ diffuse	+ radicular/sclerotomal
Limitation of movements	+ in all directions	+ only in some directions
Neurologic symptoms and signs	Negative	May be present

Table 5: Special Situations

Work related
- Lifting/bending

Childhood and adolescence
- Developmental anomalies
- Infections
- Malignancies
- Carrying heavy school bags

Young adults
- Spondyloarthropathies
- Ligament injuries
- Prolapsed intravertebral discs
- Increased computer usage

Pregnancy
- LBP
- Hyperlordosis
- Muscle stretching
- Pelvic instability
- Myofascial pain

Middle-aged
- Degenerative
- Posterior facet arthropathy

Elderly
- Osteoporosis + fracture
- Degenerative
- Malignancy

INVESTIGATIONS

It needs to be emphasised that investigations play a minimal role in low back pain, especially acute LBA which has a tendency to spontaneous recovery. Investigations may be needed to rule in or rule out 'red flag' conditions. Over reliance on radiographs should be avoided. Evident radiographic abnormalities are often not responsible for back pain. Similarly in chronic LBP, imaging studies should only be obtained if results are likely to influence surgical or medical treatment. However, patients with history of trauma or pointers towards systemic disease need appropriate laboratory investigations and radiological work-up.

Laboratory Investigations

The following laboratory abnormalities reflect a serious underlying pathology. High erythrocyte sedimentation rate, C-reactive protein and low haemoglobin occur in inflammation, malignancy and in systemic disorders. Elevated serum alkaline phosphatase is commonly seen in metastases, osteomalacia and Paget's disease and elevated serum acid phosphatase or prostate-specific antigen in prostatic cancer. The 'M' band in serum electrophoretic pattern is seen in multiple myeloma.

Radiological Investigations

The basic screening procedure is plain radiograph. Additional investigations include computed tomography (CT), magnetic resonance imaging (MRI), myelogram, bone scan, bone densitometry and single photon emission computed tomography (SPECT). CT and MRI are of special value in evaluating the anatomical details (**Figure 5**). MRI is the modality of choice; however, the CT defines the bony architecture of the spinal canal better than MRI. Bone scan is a useful screening procedure for the diagnosis of inflammation, infection and secondaries. Bone densitometry is indicated when osteoporosis is considered. SPECT is performed when a bony abnormality is suspected. In discitis, the tracer uptake has a vertical orientation. In metastatic involvement, the area of increased uptake extends from the vertebral body into the pedicle. Fractures show linear horizontally oriented areas of increased uptake centered in the vertebral body and in the transverse process. Increased uptake centered about the disc space and also seen in and projecting beyond the surface of the vertebral body is noted in degenerative joint disease.

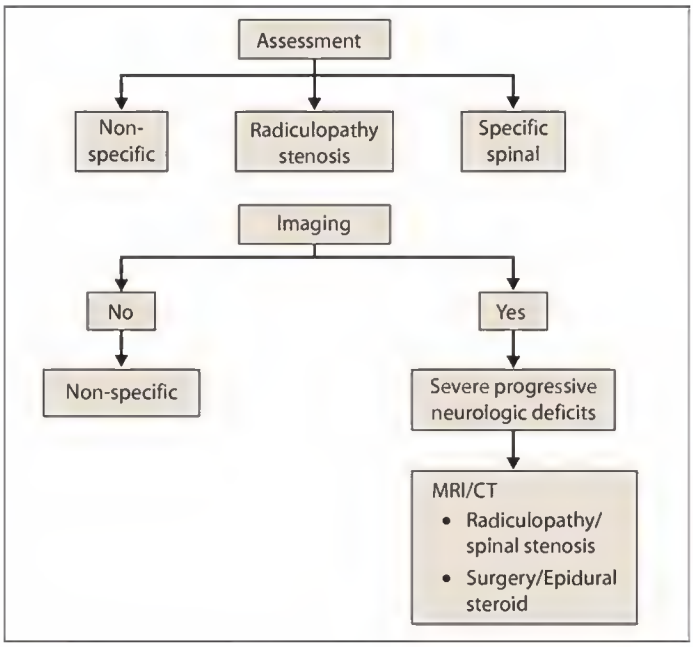

Figure 5: Clinical practice guidelines for diagnosis and treatment of low back pain (LBP).

In chronic LBP, the investigations vary depending upon the subgroups. For localised back pain, plain radiograph, CT or MRI be done. MRI differentiates metastatic spinal fractures from osteoporotic lesions. The investigation of choice for sciatica is MRI. Evaluation of anterior thigh pain includes radiographs for hip arthritis, CT with contrast in abdominal aneurysms, ultrasonogram for ureteric colic due to stone, intravenous urogram for evaluation of the urinary tract and MRI for retro-peritoneal tumours. Posterior thigh pain may need MRI or CT myelogram. Bone biopsy is indicated in rare situations when the diagnosis of the bone pathology is not clear.

The investigations of choice for the catastrophies include an urgent CT or MRI for cauda equina compression and an angiogram for ruptured aortic aneurysm.

TREATMENT

There is no single form of therapy that is effective for all forms of back pain.

Acute Low Back Pain

Cauda equina compression and abdominal aneurysm require emergency surgery, decompression in the former and resuscitation in the latter. Once the above emergencies have been ruled out, acute LBP can be treated conservatively by controlled physical activity, which refers to two days of bed rest, preferably in the semi-fowler position with the knees and hips flexed. Progressive mobilisation and exercise should follow this as the patient's pain improves. *Don't take back pain lying down* is the present trend. Physical modalities employed for mechanical low back pain include interferential therapy (IFT), transcutaneous electrical nerve stimulation (TENS), dry and moist heat, microwave and ultrasound. Functional exercises which replicate function to maximise movement, stability and offer mechanical advantage, rather than traditional ones are advocated. Analgesics (like paracetamol, tramadol, etc.) or non-steroidal anti-inflammatory drugs (NSAIDs) are used for pain relief. Local injections of cortisone or local anaesthetics, narcotic analgesics for severe pain, and muscle relaxants are also used if needed.

Back discipline (e.g. using a straight back support chair, standing on a broad base and flexing the knees while lifting weights) helps prevent recurrences.

Chronic Low Back Pain

Chronic LBP can be managed conservatively by the administration of analgesics, NSAIDs, muscle relaxants including tricyclic anti-depressants, and physical modalities like heat therapy. Early intervention in the form of spinal manipulation therapy and exercises may be more effective than bed rest and analgesics. The Mckenzie method is very effective for non-specific spinal pain.

Smoking should be avoided; obesity should be checked; correct lifting techniques and proper posture maintenance while sitting and standing should be adopted. Exercises include pelvic tilt, knees to chest, hamstring stretch and partial curl to name a few. Psychiatric counselling is given when warranted. Cognitive behavioural therapy has been proved to be useful. If conservative management fails, local or epidural steroids are given. Surgery in the form of decompression or spinal fusion is indicated when the patient develops intractable pain, neurological symptoms or deficit due to disc disease, spinal canal stenosis and unstable vertebral articulation.

Patients with persistent chronic LBP benefit from multi-disciplinary pain clinics where psychosocial approaches by interdisciplinary specialists, including occupational and vocational therapy, ergonomics and biofeedback are utilized. Acupuncture and yoga have proved to be useful (**Figure 6**).

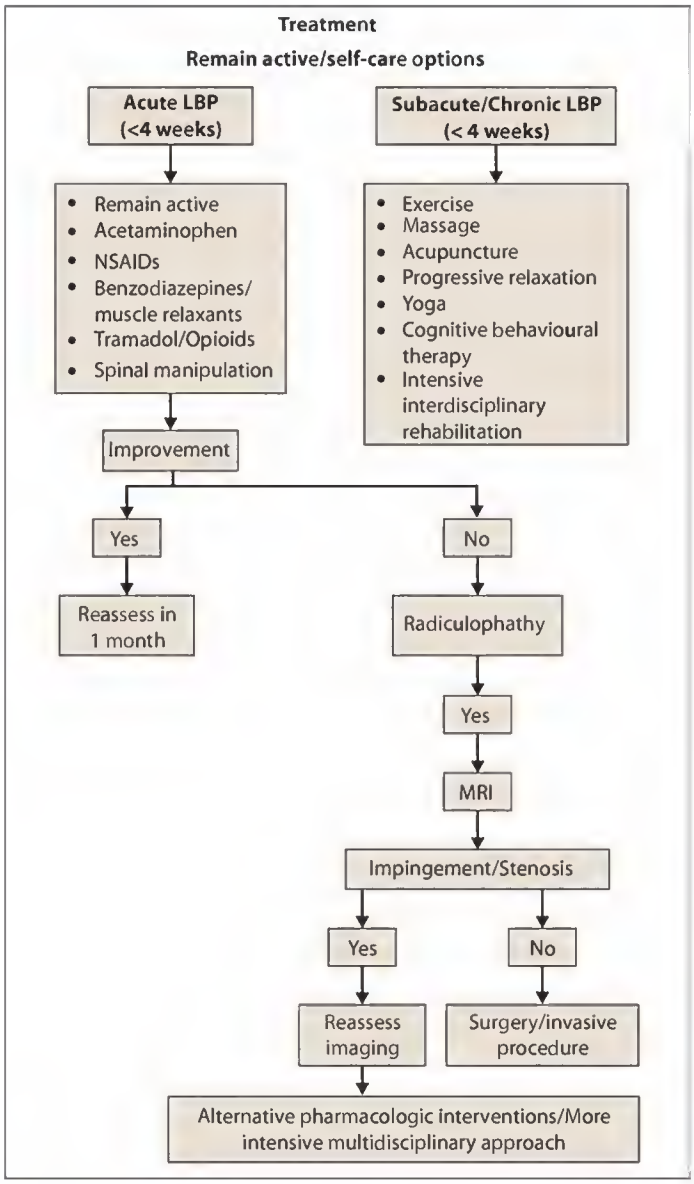

Figure 6: Clinical practice guidelines for diagnosis and treatment of low back pain.

OUTCOME MEASURES

The McGill pain questionnaire is the most commonly employed and its Indian modification in vernacular languages needs to be validated. The other common instruments used for chronic LBP are back specific function (Roland Morris Questionnaire), generic health status (SF-36), pain (Visual Analogue Pain Scale) (**Figure 7**), work disability and patient satisfaction.

The Oswestry LBP Disability Index by Fairbank *et al* interprets 'percentage of disability' as 0% to 20%—minimal; 20% to 40%—moderate; 40% to 60%—severe; 60% to 80%—crippled and 80% to 100%—bed-bound (exaggerated symptoms).

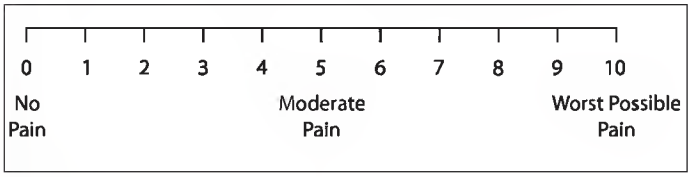

Figure 7: Visual analogue pain scale.

SUMMARY

Dealing with LBP, in general, can be arduous and taxing. Acute LBP is self-remitting in most patients as 90% improve within three months. Most back pains are mechanical in origin. Surgery for LBP is indicated only in 1% of those affected. Referrals to multidisciplinary comprehensive pain centers should be made, only after initial attempts at treatment fail. Chronic LBP may not be curable but can be surely made bearable.

24.4 Osteoarthritis

Siddharth Kumar Das

INTRODUCTION

Osteoarthritis (OA) is characterised by focal loss of cartilage with accompanying periarticular bone response in the form of subchondral bone sclerosis and attempted new bone formation by way of bony over-growths called osteophytes. OA involves all components of the joint, including bone, cartilage, meniscus and synovium. OA clinically presents as joint pain and crepitus in the elderly.

EPIDEMIOLOGY

OA is an important cause of disability and the second most common musculoskeletal problem in the world (30%) after back pain (50%). The reported prevalence of OA in rural India is 5.8%. The major risk factors associated with the knee joint OA are age, female sex, obesity, non-smoker, occupational knee bending, physical labour and chondrocalcinosis. Symptomatic and radiographic OA increases with age. The disease follows a more severe course in women with greater symptoms, more extensive involvement, and increased prevalence of knee and hand joint involvement. In contrast, men have an increased prevalence of hip OA in western countries.

Obesity precedes OA and is not its secondary consequence. Weight reduction is shown to be an effective primary as well as secondary disease prevention strategy (5% reduction in weight decreases the risk for symptomatic OA by 50%). Indians have increased knee OA as compared to Western people. This could be related to excessive squatting in day-to-day activities, especially amongst women. Hip OA is comparatively uncommon in India. Joint trauma, malalignment, meniscectomy and quadriceps weakness are important risk factors. Vitamin D deficiency, possibly acting through production of quadriceps weakness or through undefined mechanisms, has been said to be associated with progression of OA.

Chondrocalcinosis imparts a small risk, independent of age, for the development of knee OA. Chondrocalcinosis was thought to be rare in India. Although no epidemiological data is available, our recent experience suggests that it is not uncommon. Crystals are not proved to be causative but are intimately linked to the development/progression of OA.

Evidences for the genetic basis of OA are increasing. Heberden's nodes have been shown to be clustered in families with a dominant inheritance. Twin studies show 65% concordance for developing OA. Certain familial forms of OA associated with spondyloepiphyseal dysplasias are linked to a point mutation in the gene coding for type II collagen (COL2A1). An endemic variety of secondary OA has been reported from Western Karnataka (Handigodu disease) that in all probability is due to a spondyloepiphyseal dysplasia occurring in a particular community. No specific genetic abnormality has been found so far. Hand joint OA is being linked to HFE gene mutations. However, the common HFE variants C282Y and H63D are not associated with primary OA of the hip or knee. Genetic basis of generalised OA is further strengthened by its association with human leucocyte antigen HLA A1, and B8, and α1 antitrypsin M2 phenotype. Genome wide scans suggest possibility of susceptibility to be linked to chromosome 2q in the IL-1 and IL-1Ra gene region. This cluster may harbour susceptibility for knee OA but not for hip OA.

PATHOGENESIS

Normal hyaline cartilage consists of chondrocytes (1% to 2%) embedded in extracellular matrix composed of water, type II collagen and proteoglycan. The chondrocyte secretes numerous inactive matrix metalloproteinases (MMPs) that include stromelysin, collagenase, gelatinase, etc. which can destroy the whole cartilage framework. These are activated by plasmin and activated stromelysin. Chondrocytes also release tissue plasminogen activator (tPA) that converts blood or chondrocyte-derived plasminogen to active plasmin. This cascade is modulated by tissue inhibitor of MMPs (TIMP) and plasminogen activation inhibitor (PAI). Interleukin-1 (IL-1) plays a pivotal role in OA pathogenesis. It increases the synthesis and secretion of latent or inactive MMPs and tPA; suppresses proteoglycan synthesis and hence, the cartilage repair; decreases TIMP1 and PAI synthesis; and may be involved in proliferation of osteoblast-like cells leading to osteophyte formation. Matrix repair is stimulated by insulin-like growth factor (IGF-1), fibroblast growth factor (FGF) and transforming growth factor-β (TGF-β) which increase proteoglycan synthesis (**Figure 1**). In early stages there is matrix and cartilage degeneration on the one hand and active chondrocyte replication with enhanced biosynthesis on the other hand. This leads to a state of homeostasis, known as compensated OA, in which both repair and degeneration are balanced. After a few years, the reparative process is exhausted resulting in progressive OA.

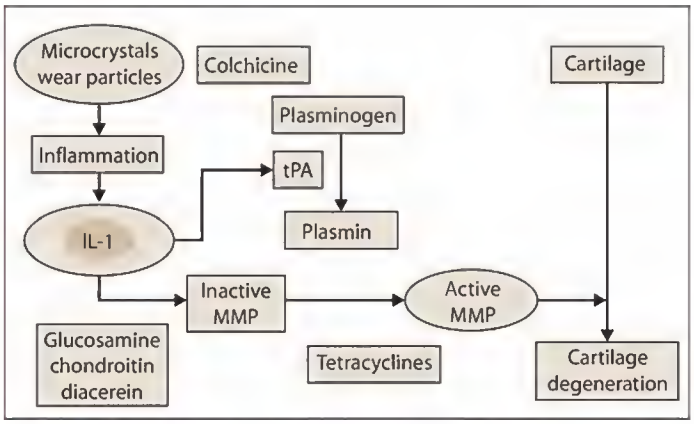

Figure 1: An overview of probable degradative mechanisms involved in OA and possible sites of action of drugs for osteoarthritis.

Previously, OA was considered to be an inherently non-inflammatory disorder. However, about 25% patients of OA of

the knee present with clinical evidence of inflammation that may be secondary to release of IL-1.

The cartilage is devoid of nerve endings. Hence, the pain in OA is believed to originate from the capsule, synovium, periosteum, subchondral bone, ligaments, muscles, etc.

MORPHOLOGY

Earliest identifiable changes are loss of proteoglycans and decreased metachromasia in cartilage. There is focal loss of cartilage, associated with reactive proliferation of chondrocytes to form clusters. Progression of these changes leads to breach of surface integrity, fissures, pitting, flaking of cartilage and development of vertical clefts (fibrillations). These fissures deepen and may expose the subchondral bone, which becomes ivory-like due to thickening and vascularisation (eburnation). Associated bone growth in subchondral region leads to sclerosis, while growth in joint margin leads to the formation of osteophytes.

NATURAL HISTORY

The course of OA is highly variable, with radiological progression seen in one-third to two-third of patients. Improvement is rare. Symptoms may progress, improve, or may even be arrested spontaneously and do not correlate well with radiographic progression.

CLINICAL FEATURES

Pain in or around the involved joints is the cardinal symptom. Usually it starts insidiously as intermittent, localised, deep ache, often aggravated by joint use and relieved by rest, in an asymmetric fashion and then becoming symmetric. The pain becomes persistent and in advanced cases night pain may be very disturbing. Knee joint involvement is typically associated with pain on descending or ascending stairs, squatting for toilet, climbing into autorickshaws, rickshaws, buses, etc. There may sometimes be locking or buckling of knee joint. Hip involvement causes problems of gait and pain in the groin or medial part of thigh.

Stiffness in joints on first awakening (morning stiffness) in OA usually lasts 5 to 30 minutes (average 20 minutes). Stiffness occurring after periods of rest or inactivity (gelling) is frequent and lasts for a few minutes. Functional impairment in OA is variable and depends on associated muscle wasting, weakness, and on radiological severity of the disease.

Signs of OA include bony swelling, crepitus (sensation of bone rubbing against bone on movement), restricted movement, deformity of joint, muscle weakness and muscle wasting. Commonly involved joints in OA are the knee, the hand joints (distal interphalangeal, first carpometacarpal and proximal interphalangeal joints) and spinal apophyseal joints, while hip, acromioclavicular, and sternoclavicular involvement is uncommon. The carpal joints, the elbow, ankle, glenohumeral and the intertarsal joints are rarely involved in OA. A bowleg deformity is seen in over 50% of patients with knee OA. Signs of local inflammation like knee joint effusion may be seen in some patients.

SUBSETS OF OSTEOARTHRITIS

OA for convenience can be categorised into four major subsets, though subsets may overlap with each other.

Nodal Generalised OA (GOA)

Nodal generalised OA is seen 10 times more often in middle-elderly women. It is characterised by Heberden's nodes (bony enlargement of distal IP joint), Bouchard's nodes (bony enlargement at proximal IP joints) and familial clustering (**Figure 2**).

Figure 2: Bouchard and Heberden nodes.

Erosive OA

It is characterised by involvement of the interphalangeal joints of the hands often with florid inflammation and erosive changes that lead to deformities and ankylosis. A small proportion (15%) may evolve into seropositive rheumatoid arthritis (RA).

Isolated Knee Joint OA

It is the most common form of OA where knee may be the only joint involved. It is usually starts unilaterally in the beginning but becomes bilateral over a period of time. Obesity, female gender and knee bending are the important risk factors. It may involve predominantly medial femorotibial, lateral femorotibial or patellofemoral compartment. The involvement of patellofemoral component is tested by eliciting pain when patella is compressed against femur on active extension of knee (Shrug test).

Spinal OA

Apophyseal joint involvement is the only true form of OA of spine. Pain in bending backwards is the typical physical sign of such involvement. Intervertebral disc degeneration with osteophyte formation (**Figure 3**) is considered an integral part of OA. It is common in the lumbar (lumbar spondylosis) and the cervical (cervical spondylosis) regions, the sites of maximum spinal motion. It gives rise to local pain and/or radicular pain. Diffuse idiopathic skeletal hyperostosis (DISH) comprises of flowing calcification along the anterior longitudinal ligaments and disc margins. DISH and OPLL (ossification of posterior longitudinal ligament) are considered to be variant forms of OA.

INVESTIGATIONS

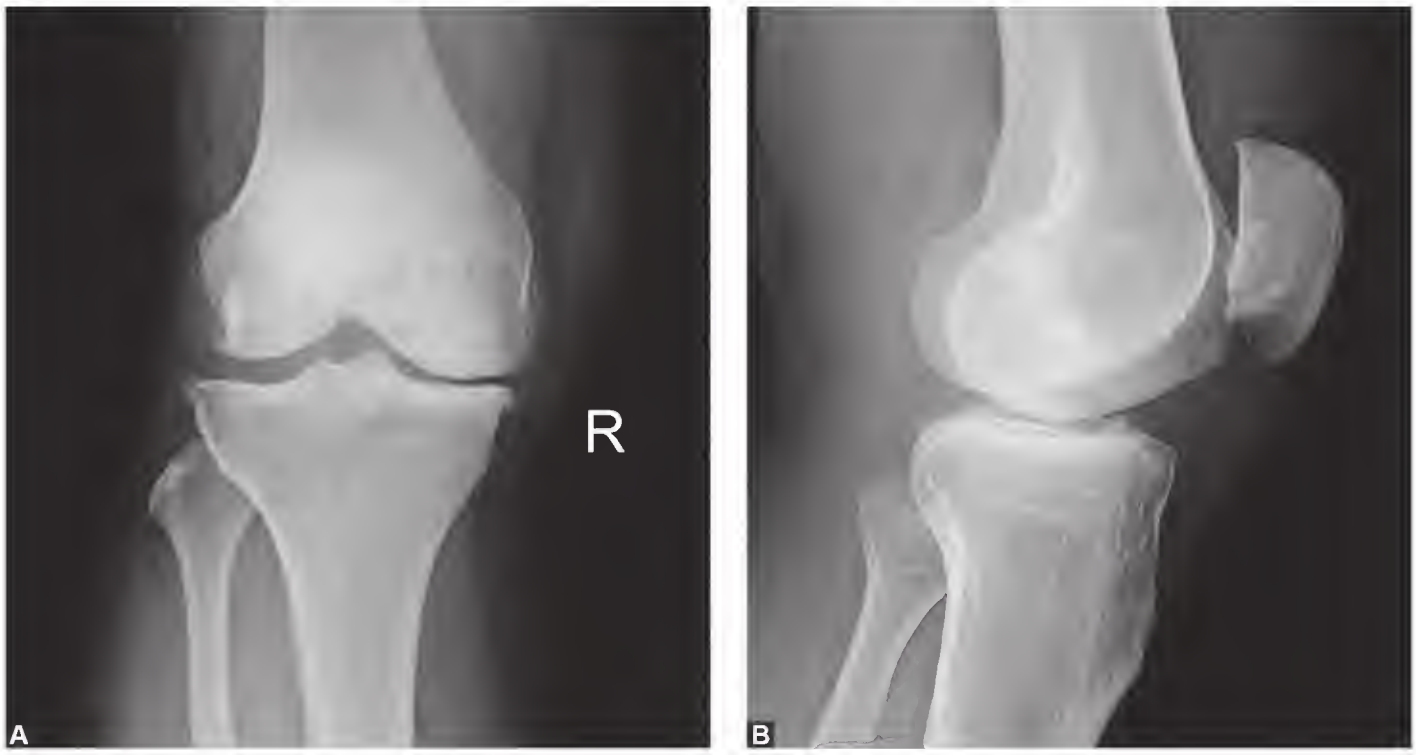
The earliest feature is joint space narrowing, which in the knee is best demonstrated in weight-bearing radiographs (**Figures 4A and B**). Osteophytes are the hallmark of the disease. Subchondral bone sclerosis, subchondral cysts, deformity, loose bodies and calcification [linear due to calcium pyrophosphate dihydrate (CPPD) deposition, spotty due to hydroxyapatite deposition] are the other changes.

Figure 3: Lumbar spondylosis.

Computed tomography is useful in assessing the axial joints. Ultrasound is useful in assessing changes in periarticular structures, like Baker's cysts. Bone marrow oedema, cartilage defects, meniscal tears, osteophytes, subchondral cysts, sclerosis, synovitis and synovial effusions may be seen on magnetic resonance imaging (MRI). MRI and Scintiscan (Tc^{99m} biphosphonate) are, however, not recommended for routine clinical use.

Synovial fluid cell count is less than 2000/mm^3 with mononuclear cell predominance. Synovial fluid may show the presence of crystals in 30% to 70% patients, commonly seen are CPPD. However, hydroxyapatite (HA) or basic calcium phosphate (BCP) crystals may also be detectable.

DIAGNOSIS



The diagnosis of OA is clinicoradiological. It is well known that early OA may not show radiological changes, while only 50% to 60% of patients with OA by radiograph are clinically symptomatic. Erosive form of OA is particularly difficult to differentiate from RA. A positive rheumatoid factor (RF) and an elevated erythrocyte sedimentation rate help in diagnosing RA. Patients having mixed disease further complicate the picture. OA changes may follow joint damage due to RA. It must be remembered that joints actively involved in RA seldom show osteophytes. The elderly may demonstrate RF positivity even in the absence of RA. Therefore, elderly patients with a positive RF, isolated knee pain and crepitus without hand joint involvement are more likely to have OA rather than RA.

MANAGEMENT

The treatment of OA is aimed at minimising pain, optimising function and reducing disability using a combination of non-pharmacological, pharmacological and surgical therapies.

Non-Pharmacological Management

Patient education and joint protection measures like avoidance of poor posture and limitation of excess joint loading are important. Day-to-day activities may need alteration (e.g. change of toilet seat from the Indian style to Western style; avoiding weight loading movements of the joints, (e.g. avoidance of squatting, sitting on low chairs, sofas, floor and climbing stairs, etc.). Weight reduction is important in obese patients. When the disease is relatively quiescent, low intensity weightbearing activity is safe and beneficial for muscle strength, mobility and a sense of well-being. But when the disease is

Figures 4A and B: Showing osteoarthritis of the right knee with: space reduction in medial compartment (A); chondrocalcinosis seen on lateral view of knee joint (B).

active with significant pain and inflammation, patients should not overstress with exercise. Quadriceps strengthening exercises are important. Supportive devices are often an adjunct to other modalities. Devices like canes, crutches, orthotic shoes and knee braces when used properly, lead to pain relief with improved function. A ¼ inch lateral heel raise or shoe insert is frequently helpful in varus deformity of knees.

Application of superficial heat on periarticular tissue by hot packs and paraffin baths alleviates pain, relieves muscle spasm and decreases joint stiffness. Deep heat by ultrasound and diathermy may damage cartilage and should be avoided. Heat increases inflammation, hence, ice packs are more helpful for acutely inflamed knee or bursae.

Pharmacological Management

Analgesics and nonsteroidal anti-inflammatory drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are used to treat the both pain and inflammation in OA. Their use is limited by their gastric and renal toxicity, especially in the elderly. Some studies have shown acetaminophen (paracetamol) 1 g 3 to 4 times a day (maximum 4 g per day) to be equally effective as other NSAIDs in OA with the advantage of fewer gastric side effects. NSAIDs like aspirin and indomethacin which have been implicated in cartilage degeneration are best avoided in OA. Newer selective cyclooxygenase-II (COX-2) inhibitors like meloxicam, celecoxib, etoricoxib, etc. have been shown to be chondroneutral and equally effective with fewer NSAIDs-related side effects. Capsaicin cream on topical application gives relief from pain and tenderness by depleting substance P in sensory nerve endings and may be used. Absorption of locally applied NSAIDs may be erratic but may have a strong psychological value.

Chondroitin and glucosamine

Chondroitin and glucosamine are nutraceutical agents whose use and effectiveness have been debated with conflicting reports in the literature. Glucosamine sulphate is given in doses of 1500 mg per day and chondroitin 1200 mg per day. They may provide symptomatic benefit in some patients with knee OA. It is unclear whether they have a disease modifying role. The sulphate salt of glucosamine marketed by one pharmaceutical company only has been shown to be consistently effective in OA and also been shown to provide disease modification. However, the hydrochloride salt has never been shown to benefit patients.

Diacerein

Diacerein in doses of 50 mg twice daily with meals is being used in OA. Diacerein has a small, consistent benefit in improvement of pain. It is believed to be an inhibitor of IL-1.

Intra-articular treatments

Intra-articular steroids are employed in patients with knee OA who have effusion. Since repeated steroid injections may lead to more cartilage damage, it is recommended that the same joint should not be injected more than 3 times a year. The incidence of joint infection following intra-articular steroids is low. Visco-supplementation with intra-articular hyaluronan injection is a promising therapy, providing symptomatic relief to about 60% to 70% patients with knee OA especially those without effusion. Hyaluronan is given as 3 to 5 (depending on molecular weight) intra-articular injections at weekly intervals. Local reaction may occur in up to 8% patients. Considering that IL-1 is an important cytokine for the development and progression of OA, anakinra has been used intra-articularly. Early studies have shown that its use is safe but a single injection with a half-life of a few hours is not effective in reducing the pain.

Colchicine

One centre from India has reported that patients presenting with significant inflammation with demonstrable CPPD crystals in joint fluid have better symptomatic relief when treated with colchicine. Even in patients not presenting with inflammation, colchicine produces significant symptomatic relief. Colchicine is used in a dose of 0.5 mg twice daily.

Other modalities

Tetracyclines chelate metals and thus inactivate MMPs. Since MMPs are important in the degradative pathway, doxycycline has been used for the management of OA. Chondrocyte transplants directly or in scaffolds, have been shown to regenerate near-normal hyaline cartilage and may be useful for small lesions of the cartilage but are not currently routinely recommended for the treatment of OA.

Surgical Management

Joint replacement must be considered in any patient presenting with end-stage joint disease with pain not responding to conventional treatment. Total knee replacement is opted by patients who are older and have weakness, more difficulty in getting up, more problems in climbing stairs and impaired extension of knee. Total hip and knee joint replacement have improved the quality of life and decreased the morbidity due to OA. Most series report excellent long-term results in over 90% of patients undergoing joint replacements. Other surgical therapies available for OA are loose body removal, osteotomy, arthrodesis, arthroplasty, synovectomy, debridement, etc. with varying grades of efficacies.

PREVENTION

Weight reduction is the only known method of reducing the risk of symptomatic OA. Lifestyle changes, like less squatting and less stair climbing, are likely to help. Some of the therapies described for OA possibly reduce the progression of OA, and hence, are more likely to be beneficial for prevention rather than for treatment. However, one has to realise that if prevention of OA is to be attempted the effort has to start in twenties and thirties, as we know that the seeds of OA are sown early.

24.5 Gout and Other Crystal Arthritides

URK Rao

Many crystals are associated with articular syndromes (**Table 1**). In practice, only monosodium urate monohydrate (MSU), calcium pyrophosphate dihydrate (CPPD), and calcium hydroxyapatite (BCP) are commonly encountered.

Table 1: Crystal Associated Arthritides

Crystal	Clinical features
Monosodium urate (MSU)	Acute/chronic gouty arthritis, tophi, renal calculi
Calcium pyrophosphate dihydrate (CPPD)	Acute pseudogout, chronic inflammatory or degenerative arthritis; chondrocalcinosis
Basic calcium phosphate hydroxyapatite (BCP)	Calcific periarthritis, acute/chronic inflammatory or destructive arthritis, soft-tissue calcinosis
Calcium oxalate aluminium phosphate	Acute arthritis in patients on renal dialysis
Cholesterol	Chronic synovial effusions in RA/OA
Cysteine/cystine	Acute arthritis
Charcot-Leyden (lysophospholipase)	Synovial fluid and tissue deposition, with eosinophilia
Xanthine	Acute arthritis (rare), renal calculi

GOUT

Gout is an inflammatory response to the MSU crystals formed secondary to hyperuricaemia. The major clinical manifestations are acute synovitis, chronic erosive and deforming arthritis, tophi, nephrolithiasis, and interstitial nephritis. The epidemiology of hyperuricaemia is different from that of gout. Mean uric acid (urate) concentrations are age and sex related. Prepubertally, in males the mean concentration is around 3.5 mg/dl, with a steep rise to 5.2 mg/dl at puberty. In females, the mean concentration is up to 4.7 mg/dl with rise only after menopause. Hyperuricaemia is defined as a serum or plasma urate concentration greater than 7.0 mg/dl in males and 6.0 mg/dl in females. Gout is seen in only one-tenth of patients of hyperuricaemia. The incidence of gout varies in population from 0.2 to 3.5 per 1000, with an overall prevalence of 2-26 per 1000. Gout is found to have increased prevalence in recent years. It is rare in children and premenopausal females. The peak age of onset in males is between 40 and 50 years.

Pathogenesis of Urate Crystal-Induced Inflammation

Uric acid is a weak acid, present mainly as urate, the ionised form in physiologic fluids. At concentrations greater than 6.8 mg/dl, urate can crystallise as MSU in and around joints. MSU crystals are released into the joint cavity, activate synovial lining cells, recruit and activate mastocytes and peripheral blood monocytes. At the cellular level, inflammation induced by urate crystals is brought by innate immune engagement of the crystals by plasma membrane receptors including toll-like receptors (2 and 4). In turn, they produce various cytokines such as interleukins (e.g. IL-1, IL-8) and chemokines leading to endothelial cell activation. Neutrophils are recruited into the joint cavity, leading to MSU crystal phagocytosis and cell activation. Auto-limitation of active inflammation is brought out by macrophages, neutrophil necrosis and apoptosis.

Risk Factors

Serum uric acid concentration is the single-most important determinant of the risk of developing gout. With normal renal function, its blood concentration depends mainly on the breakdown of nuclear proteins and dietary purine load (**Figure 1**). Provocative factors include alcohol, dietary excesses, surgery, trauma, sepsis, stress, starvation, dehydration and drugs like diuretics, pyrazinamide and aspirin.

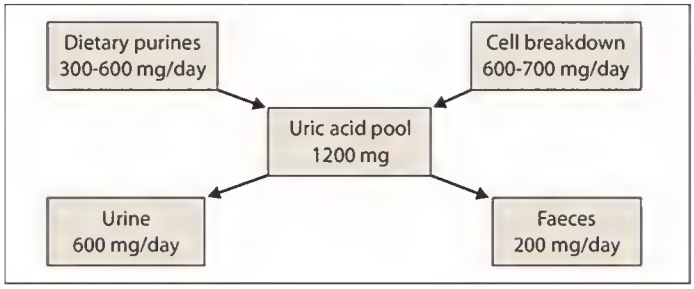

Figure 1: Body uric acid pool.

Classification

Hyperuricaemia and gout may be classified as primary and secondary (**Table 2**). Increased production of uric acid as a cause of gout is seen in only 10-15% of subjects (over-producers) and in 80-90%, uric acid excretion is impaired (under-secretors).

Clinical Features

Gout can occur in four phases.

Asymptomatic hyperuricaemia

Hyperuricaemia may be an incidental finding and may never lead to gout. Conversely, serum uric acid levels may not be elevated during acute gouty arthritis. This is because ACTH released in response to stress is uricosuric. Generally, asymptomatic hyperuricaemia needs close observation with no active treatment. However, growing epidemiological and experimental evidence indicates that asymptomatic hyperuricaemia is capable of directly promoting hypertension and vascular disease. Severe over-production of urate, as may occur with cytotoxic chemotherapy, is associated with high risk of acute renal failure and requires intervention.

Acute gouty arthritis

The big toe (first metatarsophalangeal joint) is the classic site for gout. One-third of patients may get their first attack at another site such as the in-step of the foot, ankle, knee, or hand joints. Sydenham's classic description lists the important clinical characteristics used to diagnose a typical attack. The attack is

acute, it starts in the night, the joint and surrounding tissues are swollen, hot, red, shiny and extremely painful. There is a mild fever with chills. Left untreated, the attack will start to improve in a week or two. The skin over the joint may subsequently desquamate. Atypical manifestations include tenosynovitis, bursitis, cellulitis or mild pain and discomfort without swelling, lasting a day or two. Acute gout in one joint may provoke migratory attacks affecting other joints over subsequent days (cluster attacks). Pauci or polyarticular gout attacks are more common in women, especially with diuretic use.

Table 2: Causes of Hyperuricaemia

Primary hyperuricaemia
- Increased uric acid production
  - Idiopathic (10%)
  - Specific enzyme defects
  - Hypoxanthine-guanine phosphoribosyl transferase (HGPRT) deficiency
  - Increased phosphoribosyl pyrophosphate (PRPP) synthetase activity
- Decreased uric acid excretion
  - Idiopathic (90%)

Secondary hyperuricaemia
- Increased uric acid production
  - Increased purine synthesis *de novo*-specific enzyme defects
    - Complete HGPRT deficiency
    - Glucose 6-phosphatase deficiency (type I)
  - Increased turnover of preformed purines
    - Myeloproliferative disorders, e.g. polycythaemia vera, granulocytic leukaemias
    - Lymphoproliferative disorders, e.g. lymphomas, myelomas
  - Others—Macroglobulinaemia (Waldenstrom's)
    - Carcinomatosis
    - Chronic haemolytic anaemia
    - Gaucher's disease
    - Exfoliative psoriasis
- Decreased uric acid excretion
  - Renal, e.g. chronic kidney disease, nephrogenic diabetes insipidus
  - Increased levels of organic acids, e.g. exercise, starvation, ketoacidosis and alcohol drugs, e.g. diuretics, low-dose aspirin, pyrazinamide, cyclosporine, ethambutol
  - Other medical disorders, e.g. hyperparathyroidism, myxoedema, Down's syndrome, lead nephropathy, sarcoidosis

Intercritical gout

After the first attack of gout, the second episode may never occur or occurs after several years. However, in most of the patients, the next few episodes occur within one year. The frequency of attacks and number of sites involved gradually increase with time.

Chronic gout (tophaceous gout)

Development of chronic tophaceous gout depends on uncontrolled hyperuricaemia of long duration, usually more than 10. But tophi or chronic polyarthritis may occur as early as 3 years or as late as 40 years after the first acute attack. Tophi appear as firm, nodular or fusiform swellings. In inflamed tophi, the overlying skin may be erythematous. In ulcerated tophi, white chalky material, the urate crystals, may exude. The common locations of tophi are the great toe, feet (**Figure 2**), hand joints (**Figure 3**) and olecranon. Tophi of helix of the ear, though classic is uncommon. The gout in elderly patients, especially women, may present differently compared to typical gout occurring in middle-aged men (**Table 3**).

Figure 2: Gouty arthritis affecting toes in a 45-year-old male. A tophus can be seen over the base of left great toe.

Figure 3: Gouty arthritis affecting fingers in a 45-year-old male.

Table 3: Typical Gout versus Elderly-Onset Gout

Feature	Typical Gout	Elderly-Onset Gout
Age of onset	Peak in mid 40s	Over 65
Sex	M > F	M = F
Presentation	Acute monoarthritis; lower extremity (base of greater toe, instep of the foot)	Polyarticular upper and lower extremity (finger involvement more common than typical gout)
Tophi	Several years of attack	May occur early
Associated features	Obesity, hyperuricaemia, hypertension, alcohol abuse	Renal insufficiency, diuretic use

RENAL DISEASE

After gouty arthritis, renal disease is the most frequent complication of hyperuricaemia. Urate nephropathy is attributed to the disposition of MSU crystals in the renal interstitial tissue. Other manifestations include acute uric acid nephropathy or uric acid calculi. Calcium oxalate renal stones occur more commonly in patients with hyperuricaemia or gout than in normouricaemic subjects. Renal failure accounts for 10-25% of deaths of gouty patients. Co-existent hypertension may be more important than urate in the pathogenesis of renal failure. It should be remembered that hyperuricaemia may be seen secondary to chronic renal failure without gout.

Obesity, hypertension and hyperuricaemia are important associated disorders. A negative association exists between gout and rheumatoid arthritis (RA) and gout and systemic lupus erythematosus.

Investigations

The synovial fluid is turbid with greatly elevated neutrophils. The synovial fluid should ideally be examined under polarised light. Urate crystals are needle-shaped, generally 5-25 μm in length, intracellular or extracellular in location and negatively birefringent (**Figure 4**). Urate crystals can also be demonstrated in gouty tophi.

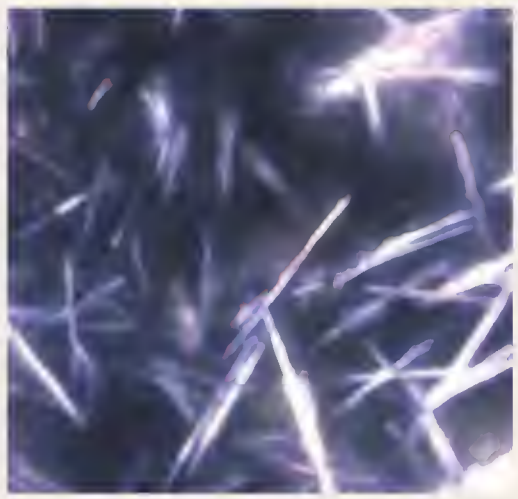

Figure 4: Negatively birefringent needle-shaped monosodium urate crystals.

Hyperuricaemia is confirmed if two or more fasting serum uric acid levels are elevated. Over-producer status can be determined by more than 700 mg in 24 hours urinary urate on a normal diet, or by a single urine sample with increased uric acid/creatinine ratio (normal <0.5). Assessment of renal function, lipid profile and acute phase reactants such as ESR help in the management.

Radiographs may be normal in early disease. In patients with recurrent attacks or chronic gout, radiographs show punched-out erosions with over-hanging edges, mostly para-articular, asymmetrical and eccentric (**Figure 5**).

Diagnosis

Demonstration of urate crystals is the 'gold standard' for the diagnosis of gout. Septic arthritis is an important differential diagnosis of acute gout. Sepsis may co-exist with gout. With less

Figure 5: Radiograph of right foot with soft tissue swelling and erosions with over-hanging edges at first MTP joint.

classic attacks, other conditions to consider are psoriatic arthritis, reactive arthritis, osteoarthritis, traumatic arthritis, pseudogout and palindromic rheumatism. Chronic tophaceous gout and polyarticular gouty arthritis are often mistaken for rheumatoid arthritis.

Treatment

The management of gout is directed towards the treatment of acute gout, prevention of further attacks and identification and correction of factors that contribute to the disease. Weight reduction and reduction of urate concentration by low purine diet should be considered in the long-term management of gout. Crash weight reduction programmes should be avoided. High purine foods are red meat, liver, kidney, sardines, pulses and whole grain cereals. If hypouricaemic agents are used, pulses may be permitted. Beer, lager, port and some wines should be avoided. Drugs such as thiazide diuretics are best avoided. Associated disorders like hypertension and hyperlipoproteinaemia should be controlled.

The drugs used are colchicine and nonsteroidal anti-inflammatory drugs (NSAIDs), xanthine oxidase inhibitors like allopurinol and uricosuric agents, e.g. probenecid and sulphinpyrazone. The sites of action of these drugs are shown in **Figure 6** and the general principles of management of gout are given in **Tables 4 and 5**.

It is important to distinguish the differences between anti-inflammatory therapy for gout and the treatment of hyperuricaemia. Allopurinol is purely a uric acid lowering agent and has no role in the treatment of an acute attack and may even precipitate an acute attack of gouty arthritis. Acute gout is treated with colchicine, NSAIDs or corticosteroids. However, if the patient is already taking hypouricaemic drugs, the same should be continued unchanged during acute attacks. A common

mistake is either to start uric acid lowering agents or to change their dosage at such times. **Table 5** gives details of drugs used to treat gout and **Figure 6** shows the site of action of drugs.

Table 4: Principles in the Management of Gout

Acute gout

- NSAIDs
- Colchicine
- Local or systemic corticosteroids

Recurrent and chronic gout

- *Reverse* factors promoting hyperuricaemia, e.g. diuretics, alcohol abuse
- *Treat* associated problems, e.g. obesity, hyperlipidaemia, hypertension
- *Correct* lifestyle patterns, e.g. avoid high purine diet, excessive exertion, starvation, dehydration
- *Use* drugs to lower plasma urate concentrations, e.g. allopurinol, probenecid
  - Allopurinol should be used in tophaceous gout and patients with renal stones. Probenecid should not be used in the presence of nephrocalcinosis or renal stones
- *Continue* prophylactic doses of colchicine or NSAIDs for a few weeks to months even after normalisation of uricaemia

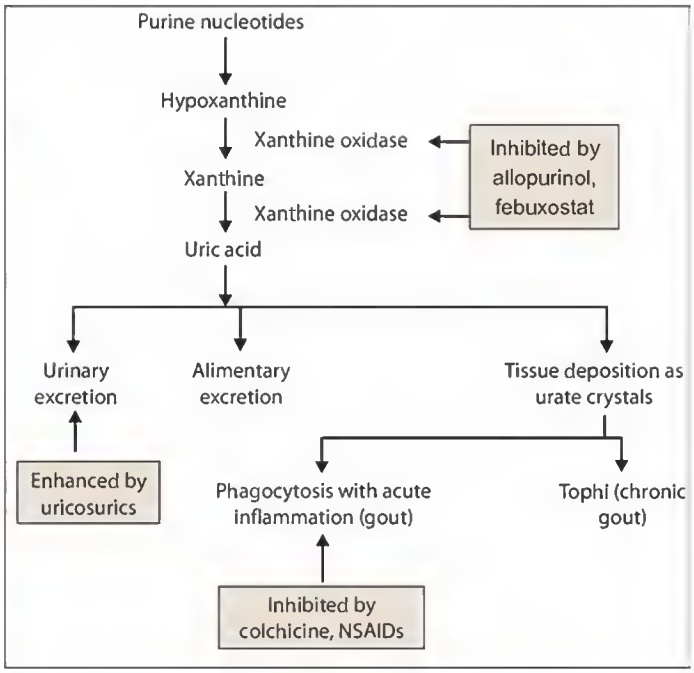

Figure 6: Sites of action of drugs in gout and hyperuricaemia.

Table 5: Important Drugs Used in the Treatment of Gout

	Colchicine	Allopurinol	Probenecid
Uses	Anti-inflammatory agent in acute gout Prophylactic drug to prevent recurrent attacks	Reduce serum and urine urate concentration in hyperuricaemia of tumour lysis, acute uric acid nephropathy, renal calculi of urate and calcium crystals in primary and secondary gout, tophaceous gout	Increases excretion of uric acid by kidney, thereby reducing serum concentration in hyperuricaemia
Mode of action	Inhibits phagocytosis by multiple actions over neutrophil leucocytes	Inhibits xanthine oxidase, its metabolite oxypurinol is active	Competitive inhibition of tubular reabsorption of urate
Dosage	In acute attack, initial dose 1 mg followed by 0.5 mg every 3 hours till desired effect or appearance of side effects; not more than 3-4 mg/day, prophylactic dose 0.5 to 1 mg/day for several months	Once or in divided doses usually up to 300 mg/day (maximum 600 mg/day)	250 mg twice a day in increments up to 1 to 2 g/day in 2 to 3 divided doses
Side effects	Vomiting, diarrhoea, haemorrhagic gastroenteritis; on larger doses myoneuropathy	Hypersensitive reactions, interaction with mercaptopurine and azathioprine; potentiates their effects	Dyspepsia, rash, convulsions, drug interactions; promotes efficacy of frusemide, indomethacin, dapsone, heparin, ampicillin
Special precautions	Dose should be reduced in renal insufficiency	Dose should be reduced in renal insufficiency. Not to start in acute gouty attack, use after inflammation subsides	Not indicated in presence of renal calculi or renal insufficiency and blood dyscrasias

Hyperuricaemia

Asymptomatic hyperuricaemia needs no drug therapy. However, prophylactic allopurinol is used to prevent uric acid nephropathy due to tumour lysis following chemotherapy. The decision to introduce drugs like allopurinol to normalise hyperuricaemia depends in part on the number of previous attacks of acute gout, the degree of hyperuricaemia (serum uric acid >10 to 11 mg/dl requires treatment) and the presence of risk factors. Urate lowering drugs are not indicated after just a single attack of gout but should be considered after a second or third attack. Allopurinol is instituted 10 to 15 days after resolution of inflammation by NSAIDs or colchicine. Anti-hyperuricaemic therapy is usually given indefinitely. **Figure 7** shows the line of action for treatment of gout.

Acute gout

Drug therapy should be initiated as early as possible. When used within the first few hours of an attack, NSAIDs or colchicine give a good response. Though indomethacin is widely used, other NSAIDs like diclofenac, naproxen, etoricoxib, piroxicam, etc. can also be used. Intra-articular steroid therapy terminates the gouty attack. This form of therapy is useful in a situation where NSAIDs cannot be given in adequate doses or are ineffective. Oral steroids may be indicated in severe acute attacks but the response is variable and rebound attacks may occur on their withdrawal.

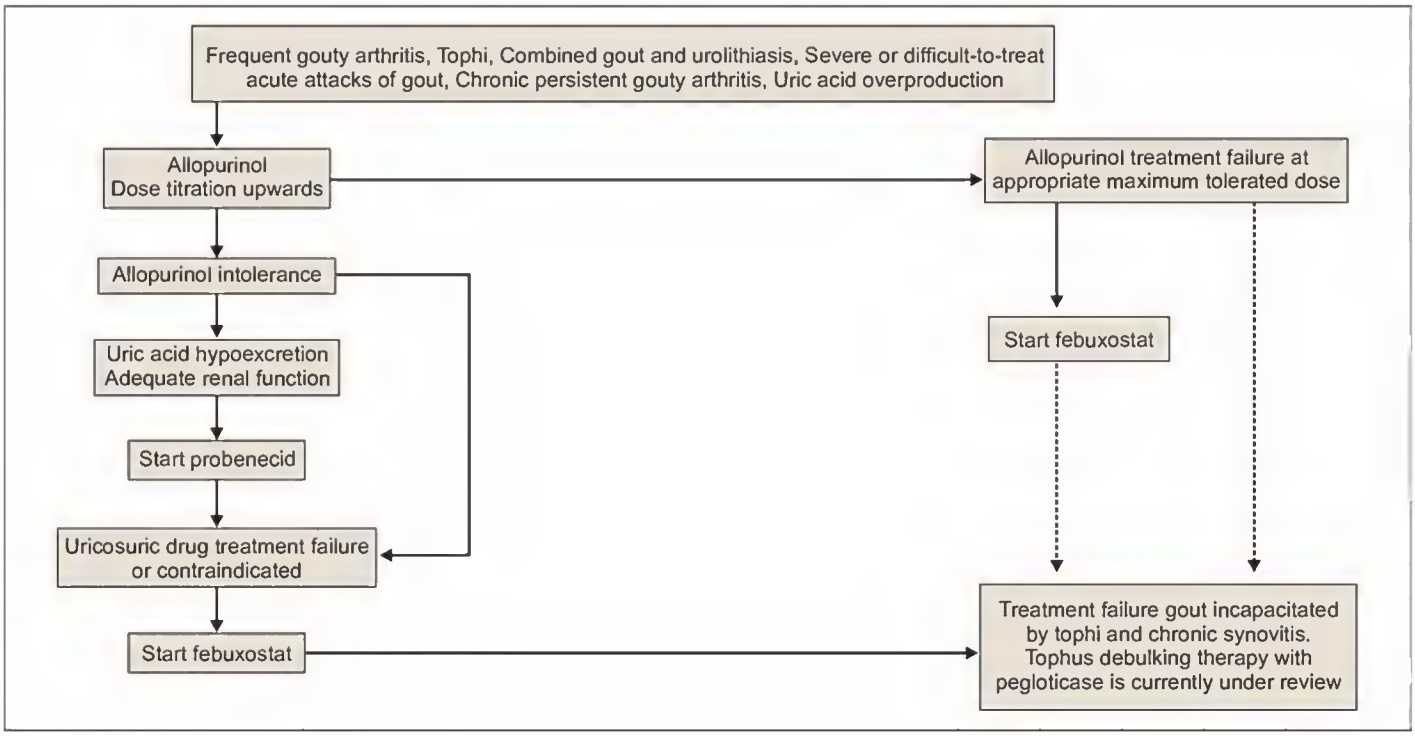

Figure 7: Therapeutic algorithm to reduce the elevated serum uric acid in gout.

Recurrent attacks of gout

Colchicine in low doses (0.5 mg twice daily) is used prophylactically to prevent recurrent attacks.

Tophaceous gout

In treating tophaceous gout, it is mandatory to lower plasma urate concentration to such a degree (<5 mg/dl) as to allow urate to be resorbed from the surface of the tophi. This requires long-term usage of uric acid lowering drugs.

Other drugs

Benzbromarone is a potent uricosuric drug used in patients with no improvement with allopurinol and in renal transplant patients. Side effects include hepatotoxicity. An angiotensin receptor blocker, losartan, used in the treatment of hypertension, has uricosuric effect. It acts by inhibiting renal tubular reabsorption of urate. Fenofibrate, a lipid-lowering drug has uricosuric effect. It is useful in the treatment of patients with hyperlipidaemia and gout.

Recent Advances in the Treatment of Gout

Febuxostat, a xanthine oxidase inhibitor (80-120 mg) has been approved and is available for the treatment of gout. Febuxostat can be used in patients with allopurinol allergy (**Figure 7**).

Recombinant uricase, Rasburicase, which metabolises uric acid, is being used to prevent development of tumour lysis syndrome in patients with malignancy on chemotherapy. Polyethylene glycol conjugated mammalian uricase (pegloticase) causes prolonged reduction of serum urate with resolution of tophi. It has been used in phase III studies in severe refractory gout. Canakinumab, a monoclone antibody which blocks ILg beta, is shown in phase 3 trials to provide rapid pain relief in acute flaves of difficult to treat gout.

OTHER CRYSTALLITIDES

Calcium Pyrophosphate Dihydrate (CPPD) Crystal Deposition Disease

Calcium pyrophosphate dihydrate (CPPD) crystals are frequently encountered in synovial fluid of patients of osteoarthritis (OA) and frequently give rise to inflammatory episodes. It is believed that CPPD crystal deposition is secondary to OA and not the primary event in such settings. A number of times, patients have primary CPPD crystal deposition before the onset of degenerative joint disease. Primary CPPD crystal deposition disease may be inherited as an autosomal dominant trait. Hyperparathyroidism, hypothyroidism, haemochromatosis, amyloidosis, hypomagnesaemia and hypophosphatasia are sometimes associated with it.

CPPD crystal deposition advances with age and 50% of those aged 90 years have radiological evidences of CPPD crystal deposition. About 20% patients with CPPD crystal deposition disease also have hyperuricaemia. Many have associated BCP crystals deposition.

Clinical Presentations

The revised diagnostic criteria of CPPD crystal deposition disease is given in **Table 6**. CPPD crystal deposition may present in several ways.

Acute pseudogout

There is inflammation of one or more joints lasting for several days to weeks. Attacks are abrupt in onset and severe. Any joint may be affected but in nearly half of the patients, the knee is the affected joint. It can occur spontaneously or after a minor trauma, surgery, illness, stroke and myocardial infarction.

Pseudorheumatoid presentation

A low-grade symmetrical polyarthritis associated with morning stiffness, fatigue, synovial thickening, flexion contractures and

Table 6: Revised Diagnostic Criteria for Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

Criteria

Demonstration of CPPD crystals in tissue or synovial fluid by definitive means (e.g. characteristic radiograph diffraction or chemical analysis)

Identification of monoclinic or triclinic crystals showing weakly positive or no birefringence by compensated polarised light microscopy

Presence of typical radiographic calcification

Acute arthritis, especially of knees or other large joints

Chronic arthritis, especially of knee, hip, wrist, elbow, shoulder, or metacarpophalangeal joint, especially, if accompanied by acute exacerbations

The following features help to differentiate chronic arthritis from osteoarthritis:

Uncommon site—wrist, MCP, elbow and shoulder

Radiographic appearance—radiocarpal or patellofemoral joint space narrowing, especially, if isolated (patella wrapped around the femur)

Subchondral cyst formation

Severity of degeneration—progressive, with subchondral bony collapse and fragmentation with formation of intra-articular bodies

Osteophyte formation—variable and inconstant

Tendon calcifications, especially triceps, achilles, obturators

Categories

Definite disease: Criteria I or II (a) plus II (b) must be fulfilled

Probable disease: Criteria II (a) or II (b) must be fulfilled

Possible disease: Criteria III (a) or III (b) should alert the clinician to the possibility of underlying CPPD crystal deposition

elevated ESR may be present in about 5% patients. About 10% patients with CPD crystal depositions may also have rheumatoid factor (RF) in low titres. Many of these patients are misdiagnosed as RA. CPPD deposition is very common, hence, RA may be present by chance in up to 1% patients of CPPD crystal deposition disease. Diagnosis of rheumatoid arthritis would be tenable in presence of high titres of RF and classical erosions.

Osteoarthritis type presentation

This is seen in about 50% of patients, the knees are the most commonly affected joints followed by the wrists, metacarpophalangeal joints, hips, shoulders, elbows and ankles. Shoulder, elbow wrist and metacarpophalangeal joint involvement is uncommon in primary osteoarthritis, and when these atypical joints are involved, it suggests the presence of a primary CPPD crystal deposition disease. Valgus deformity suggests CPPD crystal deposition disease.

Osteoarthritis with secondary CPPD crystal deposition

Patients with primary osteoarthritis usually have knee, hip, first carpometacarpal, distal interphalangeal, sometime, proximal interphalangeal joint and spine involvement (**Figure 8**). Many patients with primary osteoarthritis have radiological chondrocalcinosis. Many more (up to 60-70%) have CPPD crystals demonstrable in synovial fluids. Patients with CPPD crystals in joint fluid have more synovial effusions and more severe radiographic OA and have greater progression of disease. However, this CPPD crystal deposition is believed to occur after the start of primary osteoarthritis. Possibly, CPPD crystal

Figure 8: Calcification of lateral meniscus.

deposition disease and osteoarthritis form a continuing spectrum of disease.

Systemic Symptoms

Systemic features may appear during an acute attack of pseudogout with fever, leucocytosis and elevated ESR and acute phase reactants. Acute neck pain with fever with calcification around odontoid process (Crowned dens syndrome) may mimic pyogenic meningitis. Sometimes a picture resembling septicaemia, high fever with mental confusion and disorientation may be seen.

Neurological Manifestations

Depositions of CPPD crystals in ligamentum flavum and tumour (tophi) like CPPD crystal deposition in the spinal canal may lead to a picture of cervical myelopathy, radiculopathy and spinal canal stenosis. This may sometimes occur in the lumbar area also.

Miscellaneous Presentations

Many people with characteristic calcifications demonstrable on radiographs may be asymptomatic. Patients with back pain may present with a picture suggestive of ankylosing spondylitis with true bony ankylosis. A picture suggestive of Charcot's joint with a destructive arthropathy without neurological deficit may be seen in some patients. A monoarticular degenerative arthritis may sometimes be seen. In some patients, proximal stiffness, pain and elevated ESR may be misdiagnosed as polymyalgia rheumatica.

Diagnosis

The hallmark of the disease is demonstration of CPPD crystals in tissues or joint fluid.

Synovial fluid examination

The synovial fluid from inflamed joints is frequently haemorrhagic. Mean leucocyte concentration is about 20,000 cells/mm with predominant polymorphs. CPPD crystals are more commonly seen than radiological ch ondrocalcinosis. In

patients with acute inflammation, phagocytosed micro-crystals are seen in phagolysomomes. A phase contrast with polarised light examination gives better results. CPPD crystals may be monoclinic and triclinic and some show twining. They have a weakly positive birefringence and show inclined extinction.

Radiological Features

The typical radiological appearance of CPPD crystal deposition is called 'chondrocalcinosis'. This manifests as a linear or punctuate deposits in articular hyaline or fibrocartilageous tissues. Common sites are the knee (linear calcific deposits in femoral condylar cartilage best seen on lateral view), menisci (best seen in AP view, uncommon in India) (**Figures 8 and 9**), symphysis pubis and hips, wrists and spine (calcification of annular ligaments) (**Figure 10**). CPPD crystal deposition disease is characterised by isolated wrist degeneration and isolated patellofemoral joint space narrowing.

Treatment

Like with gout, colchicine in high doses may abort attacks of pseudogout. High-dose colchicine may be toxic, hence, intra-articular corticosteroids may be better. There is no drug treatment to remove CPPD crystals from tissues or joint fluids. Joint aspirations are the only method to remove CPPD crystals from synovial fluid and may help. NSAIDs are commonly used. Long-term oral colchicine may reduce the number and duration of acute attacks. Whether removal of crystals and prevention of acute attacks by colchicine will prevent or slow degenerative joint disease is not known.

Basic Calcium Phosphate (Calcium Apatite) Crystal Deposition Disease

Basic calcium phosphate (BCP) deposition disease is known to cause acute and chronic musculoskeletal symptoms such as bursitis and tendinitis. The recurrent painful periarticular inflammation is associated with radiographically demonstrable periarticular calcifications at multiple sites. Common sites of involvement include the shoulder, greater trochanter of the hip, lateral epicondyle of the elbow and tendinous attachments around the wrist and knee. Microscopic study reveals typical globular bodies with a 'shiny coin' appearance depicting calcium apatite crystals. Calcium and phosphorus metabolism is usually normal.

Apatite crystal-induced inflammation is also observed in patients on chronic haemodialysis and those with scleroderma or dermatomyositis. Apatite deposits can also occur intra-articularly. Erosive arthritis usually of shoulders (Milwaukee shoulder) rarely occurs in elderly women due to apatite crystal deposition.

The management of BCP deposition disease includes therapy with NSAIDs, colchicine, local glucocorticoid injections and physiotherapy.

Calcium Oxalate Crystal Deposition Disease

Calcium oxalate deposition produces an unusual form of arthritis mostly seen in patients with renal failure on dialysis, with chronic bowel disease or in primary oxalosis. Patients present with acute mono- or oligoarticular arthritis involving metacarpophalangeal joints. It may be of asymmetrical onset and associated with tenosynovitis or bursitis. Unlike gout, initial episode may be prolonged and chronic arthritis may develop rapidly. Diagnosis can be established by identifying calcium oxalate crystals which may be calcium oxalate dihydrate (positively birefringent bipyramidal crystal), or calcium oxalate monohydrate.

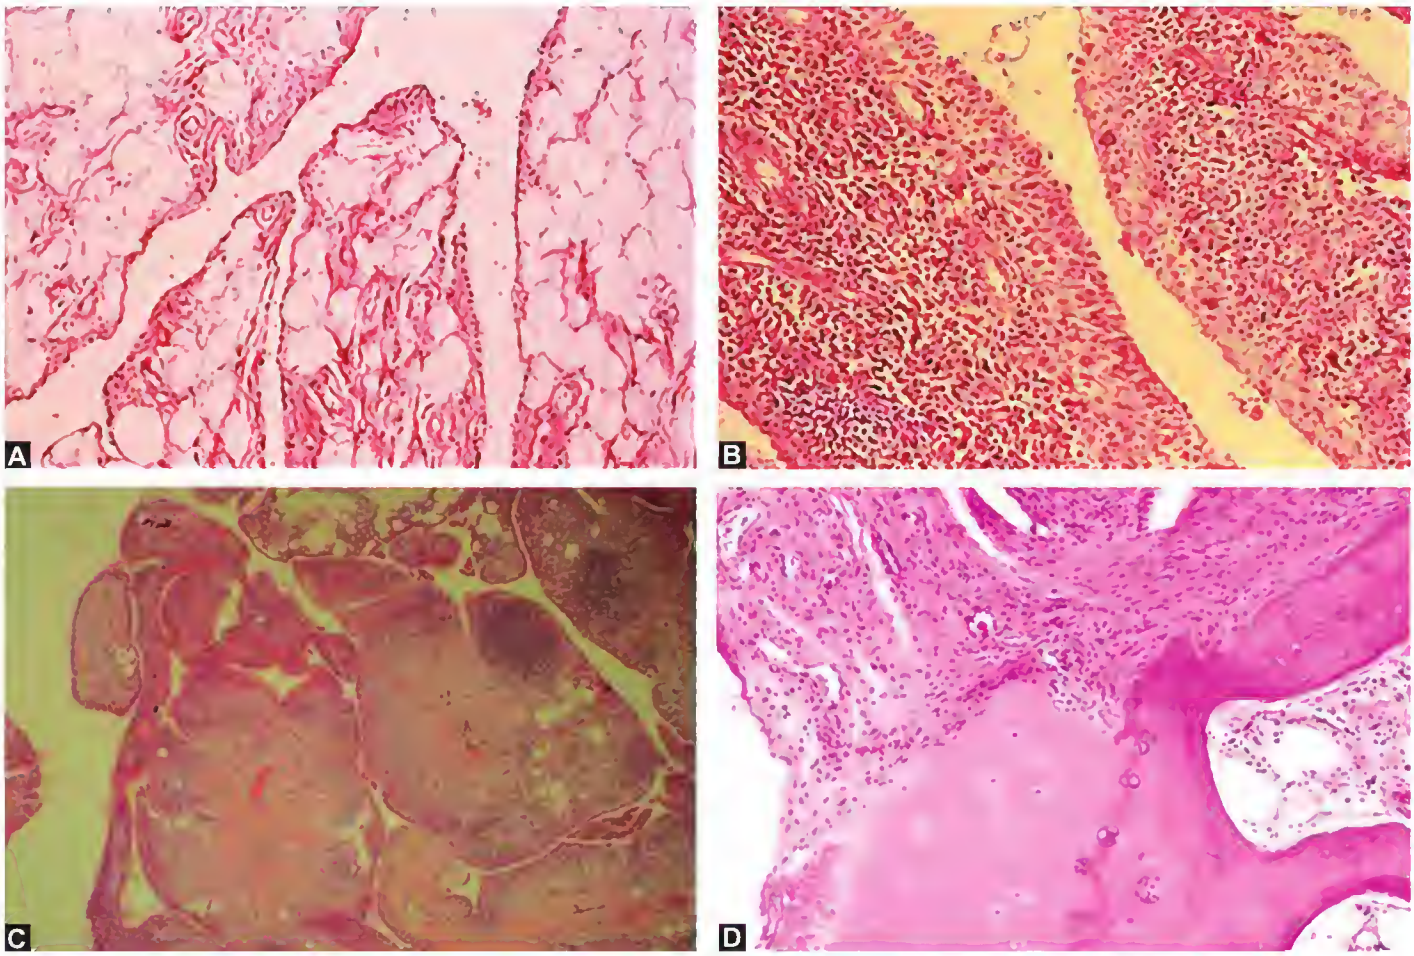
24.6 Rheumatoid Arthritis

AN Malaviya

INTRODUCTION

Rheumatoid arthritis (RA) is a chronic systemic inflammatory polyarthritis that primarily affects small diarthrodial joints of the hands and feet in a symmetrical pattern. It is a heterogenous disease with variable severity, unpredictable course, and a variable response to drug treatment.



EPIDEMIOLOGY

The disease prevalence worldwide is approximately 0.8% (0.3% to 2.1%) of the population. In India, the prevalence of RA is 0.5% to 0.75%. The peak age of onset is in the fourth and fifth decade of life with more than 75% patients developing disease between 30 and 50 years of age.

GENETIC AND RISK FACTORS

The disease is seen 2 to 4 times more often in first degree relatives. The disease concordance in monozygotic twins is approximately 30% to 50%, while it is similar to nontwin siblings in dizygotic twins. The most important genetic susceptibility locus associated with RA is a class II major histocompatibility complex (MHC) allele of man namely, HLA-*DRB1* and the group of alleles collectively identified as shared epitope (SE). These include HLA-DR4 (DRβ1*0401) and other closely related alleles (DRβ1*0101, and several others). Among Indians, genetic susceptibility to RA with highest relative risk is with DRB1*0405, followed by DRB 1*0401 and those with DR4 haplotypes on DQB1*0302 region. Interestingly certain HLA-DR alleles may be protective against RA, e.g. DRB1*1502 and DRB1*0403 among Indian RA patients.

Nongenetic risk factors include gender and tobacco. Women are affected with RA 2 to 4 times more often than men. Role of hormones, pregnancy and related physiological alterations, foetal-maternal interactions have been implicated. Recently, a link between RA and smoking has been established. Smoking causes repeated insult to the mucosa of the airways causing

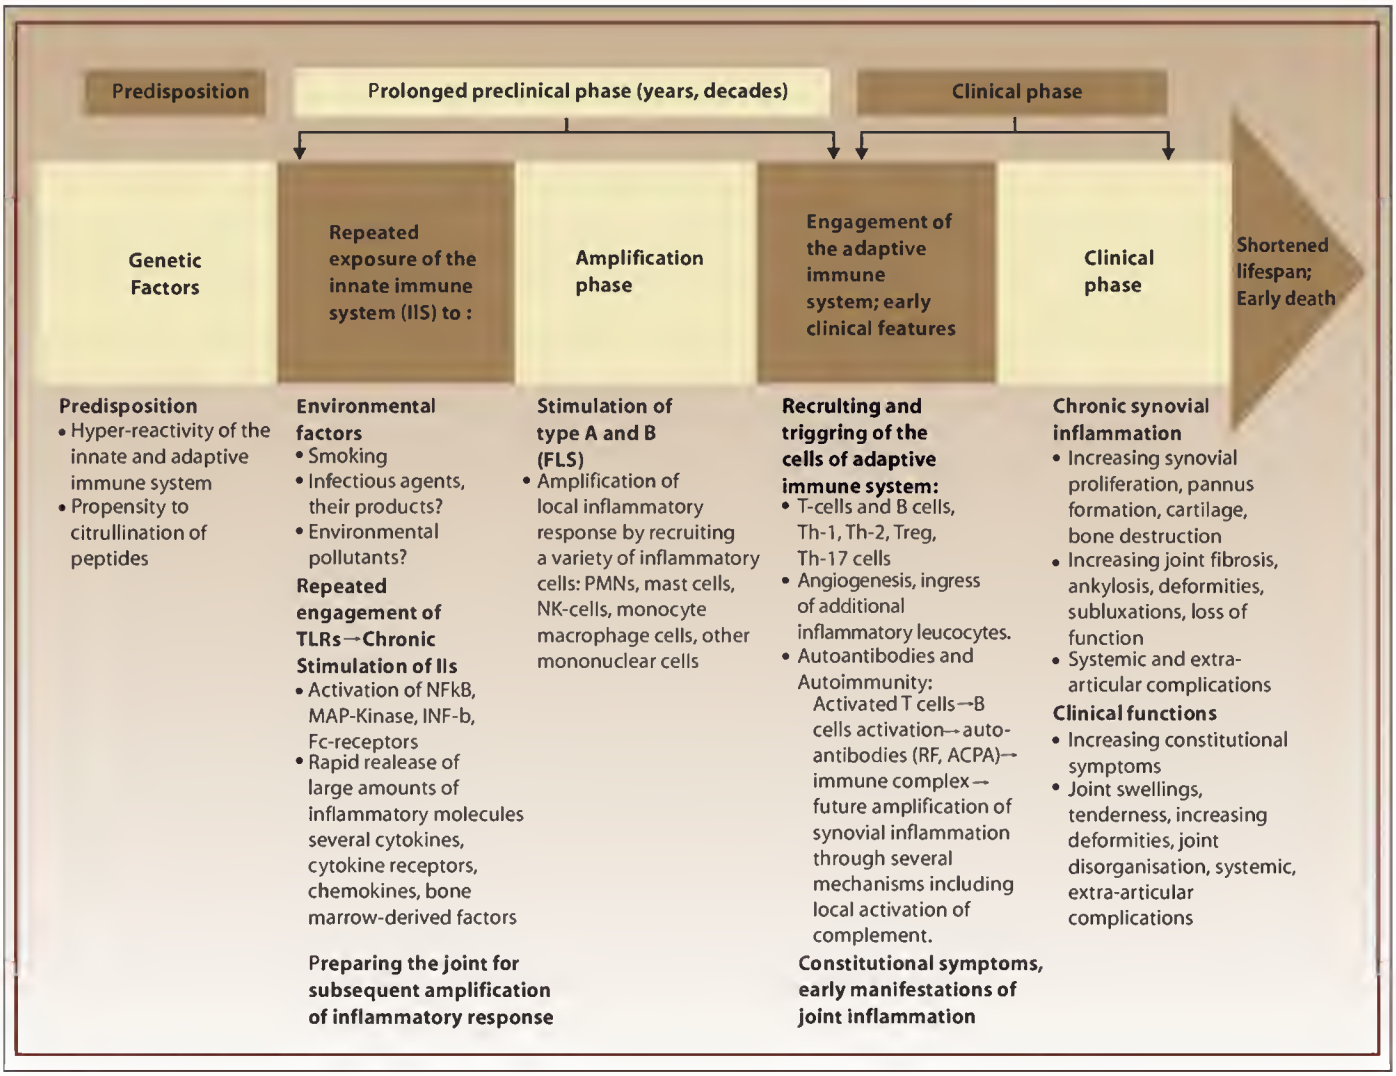

Figure 2: Natural history and immunopathogenesis of RA.

persistent low-grade inflammation that activates innate immune system through engagement of toll like receptors.

AETIOLOGY

The exact cause of RA still remains unknown. Infectious agents or their products have been implicated without conclusive evidence.

PATHOLOGY AND IMMUNOPATHOGENESIS

The synovium is the primary site of inflammation. The intimal layer becomes hypertrophied (up to 10 cell layers) with increased number of both types A and B synoviocytes. The subintimal region shows features of microvascular injury with thrombosis, neovascularisation (formation of new capillaries) and hyperplasia with increased cellularity (**Figures 1 and 2**). The proliferating synovial tissue is oedematous and overgrown with villous projections protruding into the joint cavity. This structure is called *pannus*.

Lymphocytes in perivascular lymphoid aggregates are populated with CD4+/Th1 and Th-17 T-helper memory cells. The other subsets of lymphocytes are the regulatory T cells (T_{regs}) mixed with small numbers of CD8+ cytotoxic T cells mainly found at the periphery of the lymphoid aggregates and scattered in the sublining. Besides T cells, rheumatoid synovitis also shows variable number of B cells and antibody producing plasma cells that cause polyclonal increase in immunoglobulins and production of autoantibodies.

Cytokines

TNF-α, mainly produced by synovial macrophages, is the master cytokine that triggers an inflammatory cascade. The imbalance between pro- and anti-inflammatory cytokines is an important mechanism of self-perpetuating chronic inflammatory synovitis in RA (**Figures 3 and 4**).

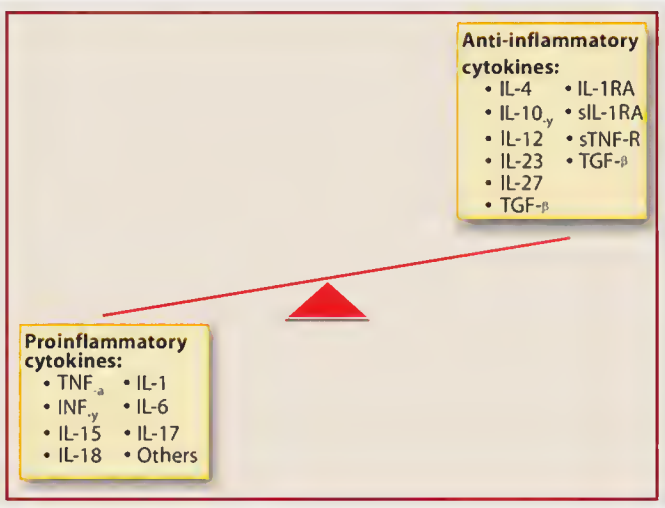

Figure 3: Cytokine imbalance in rheumatoid joint with preponderance in proinflammatory cytokines.

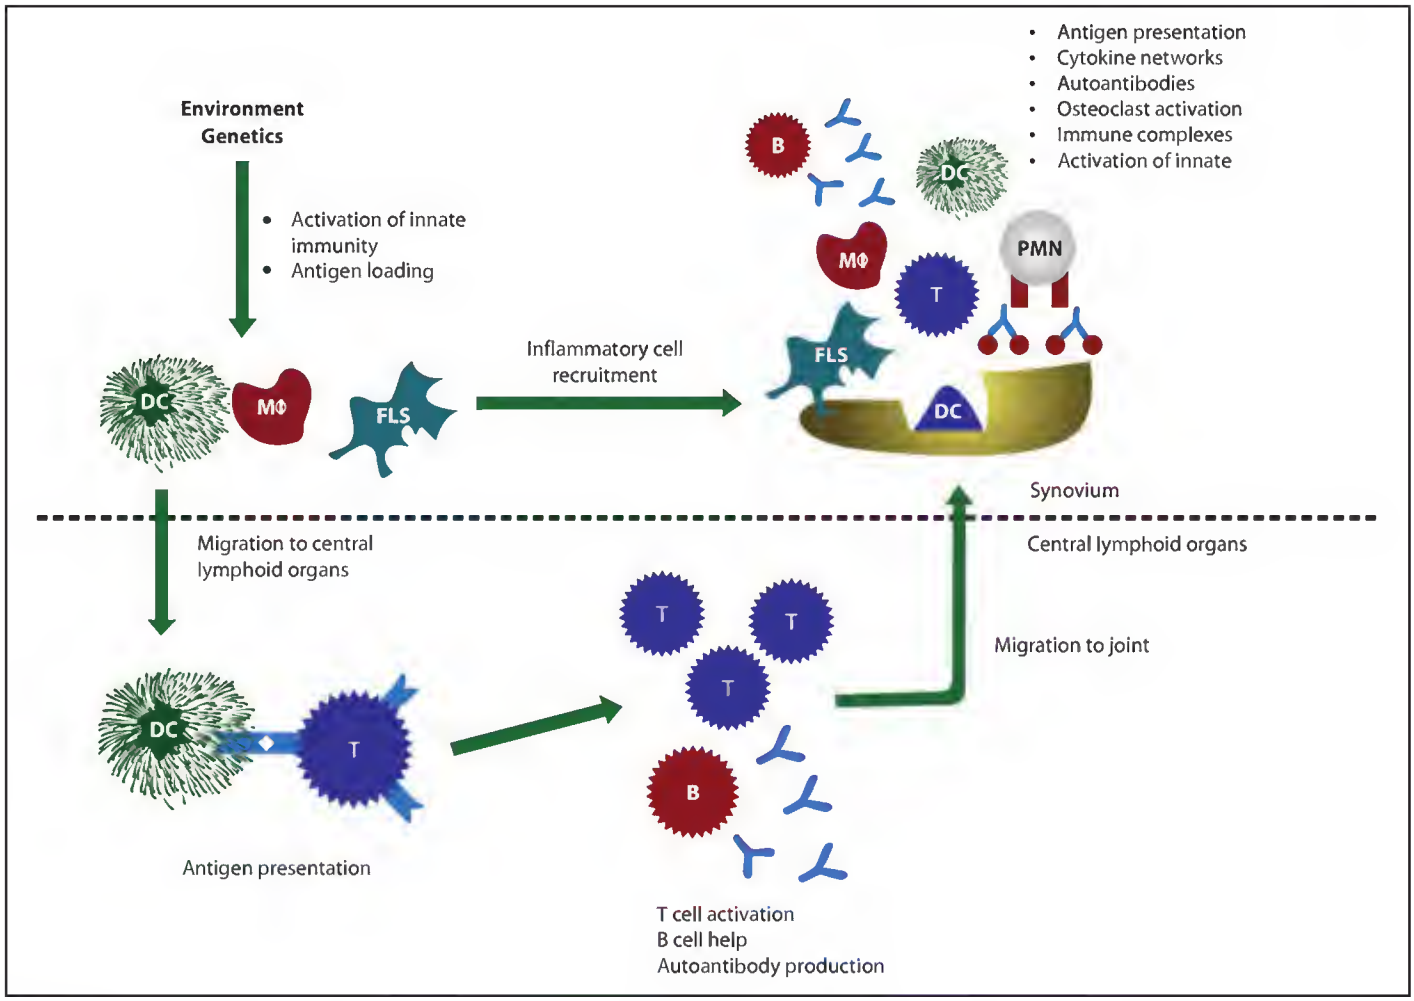

Figure 4: Immunopathogenesis of RA: Shows the current model of the immunopathogenesis of RA where both innate and adaptive immune systems co-operate and interact with each other to cause synovial inflammation in RA. The *innate immune system* is represented by antigen processing and presenting cells namely dendritic cells (DC), macrophages (MΦ), fibroblast-like synoviocytes (FLS) and polymorphonuclear leucocytes (PMN). The *adaptive immune system* is represented by T lymphocytes (T) the central cell of the adaptive immune system, B lymphocytes (B) that differentiate into antibody producing cells. Nonspecific inflammation caused by stimulation of the cells of the innate immune system, triggered by repeated exposure to environmental factors (smoking, others), and endogenous ligands, causes release of inflammatory cytokines (see Figure 3), which activate synoviocytes and macrophages to secrete chemokines and recruit T cell (of the adaptive immune system) in the joint. Locally produced autoantigens from damaged joint caused by nonspecific inflammation is processed by DC and presented in association with MHC class-II antigens, to T cells that are activated by dual signal of antigen presentation + costimulation molecule CD28. Then, activated T cells migrate out of the joint to the regional lymph nodes where they proliferate, produce a variety of cytokines, chemokines and growth factors thus recruiting and stimulating effecter T cells and B cells that migrate back to the joint. The effector T cells further amplify inflammation and provide helper signals to B cell to differentiate into antibody producing cells secreting autoantibody (rheumatoid factor [RF] and anti-citrullinated peptide antibodies [ACPA]). Autoantibodies make immune complexes activating complement cascade that further amplify inflammation. In established and late RA, local cytokine networks amplify and maintain a self-perpetuating inflammatory loop within the joint. Possibly this is aided by antigen presented by DC to T cells locally in the joints in the secondary lymphoid follicle-like structures seen in the synovial tissue at this stage. Terminal structural damage in the joint occurs through production of large amounts of proteolytic enzymes (mainly matrix metalloproteinase [MMPs], aggrecanases, collagenase, stromelysin) from pannus, PMNs and chondrocytes themselves; causing degradation of cartilage, tendon and ligaments. The invading pannus also releases cytokines namely IL-1, TNF-α that stimulate production of proteases, prostaglandins and activate osteoclasts (OC). Activated osteoclasts cause bone demineralisation (osteoporosis) and erosion. This is the end-stage joint damage of RA with erosions and irreversible structural damage leading to deformities and subluxations typical of late untreated RA. For details see text and Figures 1 to 3. (Adapted and reproduced from Waldenburger JM, Firestein GS. Rheumatoid arthritis: Epidemiology, Pathology and Pathogenesis. In: Primer on the Rheumatic Diseases, Klippel JH, Stone JH, Crofford LJ, White PH (Eds) 13th ed., Springer Science+Business Media LLC. 2008; With permission).

CLINICAL FEATURES

History

Inflammatory features include diurnal variation with symptoms, worse after a period of inactivity (e.g. early morning, after an afternoon siesta) that takes at least 30 to 60 minutes of gentle movements (e.g. taking a bath, doing daily chores) for maximal improvement, fluctuating course with disease severity varying from day-to-day, associated with constitutional symptoms of fatigue, malaise, feverish feeling (actual fever uncommon), loss of appetite and weight loss.

Pattern of Onset

Most commonly, the onset of symptoms of joint pains and swelling are insidious, evolving slowly in a fluctuating manner, over weeks to months. Much less commonly, there could be a sudden explosive onset of polyarthritis within a few days. Less common is a slow monoarticular presentation affecting larger joints such as shoulders or knees then spreading to other joints after variable periods. Still others may present with transient self-limited episodes of mono- or polyarthritis lasting days to weeks, a syndrome that is called palindromic rheumatism. Approximately 50% of such patients evolve into RA over time.

There are several uncommon modes of onset including persistent monoarthritis, abrupt acute monoarthritis of knee, shoulder or hip that may be confused with septic or crystal arthritis; persistent involvement of the joints of a single hand; inflammatory oedematous swelling on the dorsum of the hands or feet with a fluctuating course.

Joint Involvement

In early disease most commonly metacarpophalangeal (MCP) joints, interphalangeal (IP) joints of the thumbs, proximal interphalangeal (PIP) joints of fingers, wrists, mid-tarsal joints and metatarsophalangeal (MTP) joints are affected in that order (**Figure 5**). Soft swelling on the dorsum of the wrist due to tenosynovitis is an early sign. As the disease advances larger joints such as elbows, shoulders, knees and ankles are recruited. Uncommon joints to be affected in RA include hip, sternoclavicular, temporomandibular joints and joints in upper cervical spine. Rare cases have been reported with the involvement of cricoarytenoid joints in the larynx causing hoarseness of voice, interossicle joints in the middle ear causing some degrees of deafness. Typically, however, RA spares distal interphalangeal (DIP) joints and thoracolumbar spine. Thus, RA is an inflammatory joint disease characterised by symmetry, bilateralism and predilection for small joints in the hands and feet (especially in the early disease). Most of these typical clinical features of RA are incorporated in the revised 1987 American College of Rheumatology (ACR) criteria for the *classification of RA* (**Table 1**). These are not meant for making a bed-side diagnosis of RA but only for research and epidemiological studies. It is also helpful to remember that although many joints are known to get affected, the main target in RA are the 14 joint-groups namely PIP, MCP, wrist, elbow, knee, ankle and MTP. Clinical diagnosis of RA could be made if a minimum of 3 joints from these 14 joint groups are affected simultaneously for at least 6 weeks duration and show soft tissue swelling or joint effusion where at least one swollen joint is in a wrists, MCP or PIP and one of them is also present on the other side of the body (symmetrical involvement, absolute symmetry not required). The 1987 classification criteria of RA served its purpose admirably for patients with established or late disease. However, several carefully designed studies showed that it performed poorly in patients with early RA. Thus, the need for urgent revision of the old classification criteria became obvious. After more than a decade of collaborative work by rheumatologists under the aegis of the American College of Rheumatology (ACR) and European Leagues of Associations against Rheumatism (EULAR), new (2010) classification criteria for RA have been published superseding the earlier (1987) classification criteria (**Table 2**). The key points of difference from the 1987 classification criteria are as follows:

- They differ from the previous criteria in that the presence of synovitis in at least one joint is required, with no alternative diagnosis to explain the synovitis.
- Symmetric disease involvement is not required, nor is the presence of structural joint damage or rheumatoid nodules, both reflective of longstanding, established disease.

Thus, it redefines the current paradigm of RA. The other differences are:

- Their ability to utilise the diagnostic importance of antibodies to citrullinated proteins in RA (see below), advancement that was not available at the time the old classification criteria were propounded.
- Their ability to classify patients with 1-2 swollen joints and anti-citrullinated protein antibody positivity as having RA who, till recently, were labelled as having undifferentiated arthritis.
- Its ability to detect early RA that would facilitate undertaking the ideal therapeutic intervention at an early stage before the development of the final phenotype (i.e. patients with obvious joint damage); its use as a basis for initiating disease-modifying antirheumatic drug therapy at an early disease stage.

Table 1: The 1987 Revised Criteria for the Classification of RA*

Criterion	Definition
Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 hour before maximal improvement
Arthritis of 3 or more joint areas	At least 3 joint areas simultaneously have had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left proximal interphalangeal joint (PIP), metacarpophalangeal joint (MTP), wrist, elbow, knee, ankle, and metatarsophalangeal joints
Arthritis of hand joints	At least 1 joint area swollen (as defined above) in a wrist, MCP or PIP joint
Symmetric arthritis	Simultaneous involvement of the same joint areas (as defined in item 2 above) both sides of the body (bilateral involvement of PIPs, MCPs, or MTPs is acceptable without absolute symmetry)
Rheumatoid nodules	Subcutaneous nodules, over bony prominences, or extensor surfaces, or in juxta-articular regions, observed by a physician
Serum rheumatoid factor	Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive has been positive in < 5% of normal control subjects
Radiographic changes	Radiographic changes typical of RA on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localised in or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

**Adopted from Arthritis Rheum 1988;31:315-24. With permission of John Wiley & Sons, Inc. For classificotion purpose, o potient sholl be soid to hove RA if she/he hos sotisfied ot leost 4 of these 7 criterio. Criterio 1 through 4 must hove been present for ot leost 6 weeks.*

Para-Articular Involvement

A common manifestation of RA is tenosynovitis in tendon sheaths around wrists and in the hands, a major cause of hand weakness. Carpal tunnel syndrome may also be seen.

Complications in Specific RA Joints with Associated Loss of Function

Progressive disease causes progressive structural damage leading to deformities, subluxations, and finally disintegration or ankylosis of the joints. Deformities seen in established RA include 'ulnar deviation' that occurs at the MCP joints, 'swan-neck' deformity characterised with flexion of the DIP and MCP joints with hyperextension of the PIP joint, 'Boutonnière deformity', 'Z' deformity of the thumb and subluxation of the distal radioulnar

Table 2: The 2010 ACR-EULAR Classification Criteria for Rheumatoid Arthritis*

	Score
Target population (Who should be tested?): Patients who:	
Have at least 1 joint with definite clinical synovitis (swelling)	
With the synovitis not better explained by another disease†	
Classification criteria for RA (score-based algorithm: add score of categories A–D; A Score of ≥6/10 is needed for classification of a patient as having definite RA)‡	
Joint involvement§	
1 large joint¶	0
2-10 large joints	1
1-3 small joints (with or without involvement of large joints)#	2
4-10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)**	5
Serology (at least 1 test result is needed for classification)††	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
Acute-phase reactants (at least 1 test result is needed for classification)‡‡	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
Duration of symptoms§§	
< 6 weeks	0
≥ 6 weeks	1

**The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of rheumatoid arthritis (RA) with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with longstanding disease, including those whose disease is inactive (with or without treatment) who, based on retrospectively available data, have previously fulfilled the 2010 criteria should be classified as having RA.*

†Differential diagnoses vary among patients with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

‡Although patients with a score of <6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

§Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are excluded from, assessment. Categories of joint distributions are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

¶ "Large joints" refers to shoulders, elbows, hips, knees, and ankles.

"Small joints" refers to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

***In this category, at least 1 of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g. temporomandibular acromioclavicular, sternoclavicular, etc.).*

††Negative refers to IU values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are higher than the ULN but ≤3 times the ULN for the laboratory and assay; high-positive refers to IU values that are >3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RF. ACPA = anti-citrullinated protein antibody.

‡‡Normal/abnormal is determined by local laboratory standards. CRP = C-reactive protein; ESR = erythrocyte sedimentation rate.

§§Duration of symptoms refers to patient self-report of the duration of signs or symptoms of synovitis (e.g. pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

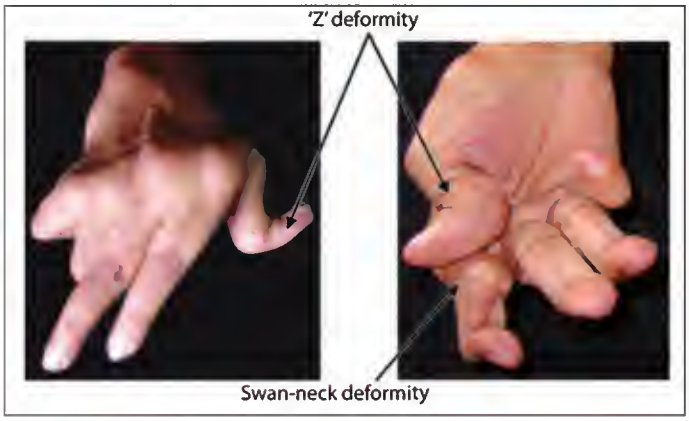
joint (**Figures 5 to 10**). More than one-third RA patients have significant foot disease like 'cock-up' toe deformity, hammer toes and 'rocker bottom' deformity (**Figures 11A to C**).

Figure 5: Typical physical findings of moderate swellings in the metacarpophalangeal and proximal interphalangeal joints in a patient with established RA.

Figure 6: The ulnar deviation (ulnar drift) of the fingers at the metacarpophalangeal joints in a patient with late RA.

Figure 7: The 'Swan-neck' deformity of the fingers in a patient with late RA.

Figure 8: The Boutonnière deformity in the finger joints; ulnar deviation (at MCP joints) is also seen.



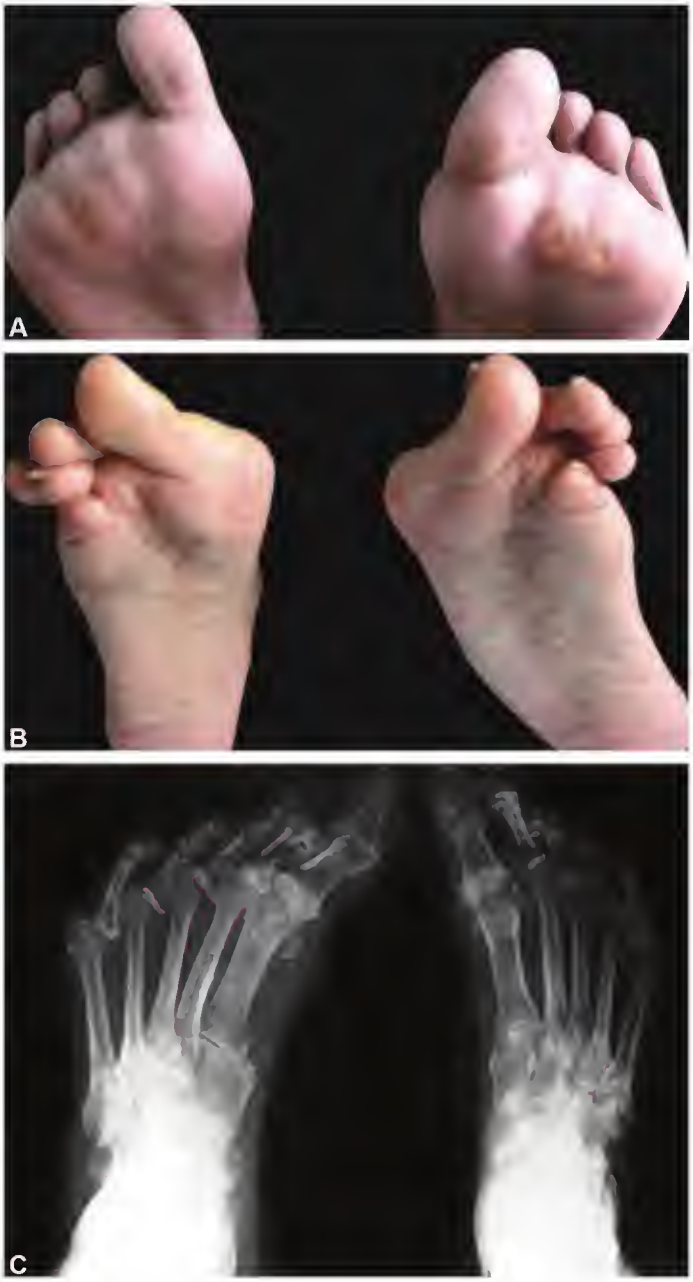


Figure 9: The 'Z' deformity in the right thumb; also note 'swan-neck' deformities in some of the fingers.

Figure 10: Late RA with advanced subluxation of the metacarpophalangeal joints with ulnar deviation and wrists with wasting of the small muscles of the hands. Note the 'squaring'-deformity of the left wrist and swan-neck deformity of the left little finger.

Figures 11A to C: Typical deformities in the forefeet in RA.

Extra-Articular Features

These include:

Rheumatoid nodules

These are firm nontender subcutaneous that tend to develop over pressure areas of the body most common being elbows and extensor surface of the proximal forearm (**Figure 12**). Other sites for rheumatoid nodules are Achilles tendon, fingers, occipital region on the scalp, and ischial tuberosities. Studies on RA from India have reported very low prevalence of rheumatoid nodules (~3%) that are very often unilateral.

Eye

Involvement of the lacrimal glands causes dryness in the eyes (keratoconjunctivitis sicca). Redness, pain, gritty feeling and excess mucous collection in epicanthus on getting up in the morning are the usual complaints. Usually there is associated parotid and minor salivary gland involvement causing dryness of mouth. Scleritis and episcleritis are the other less common

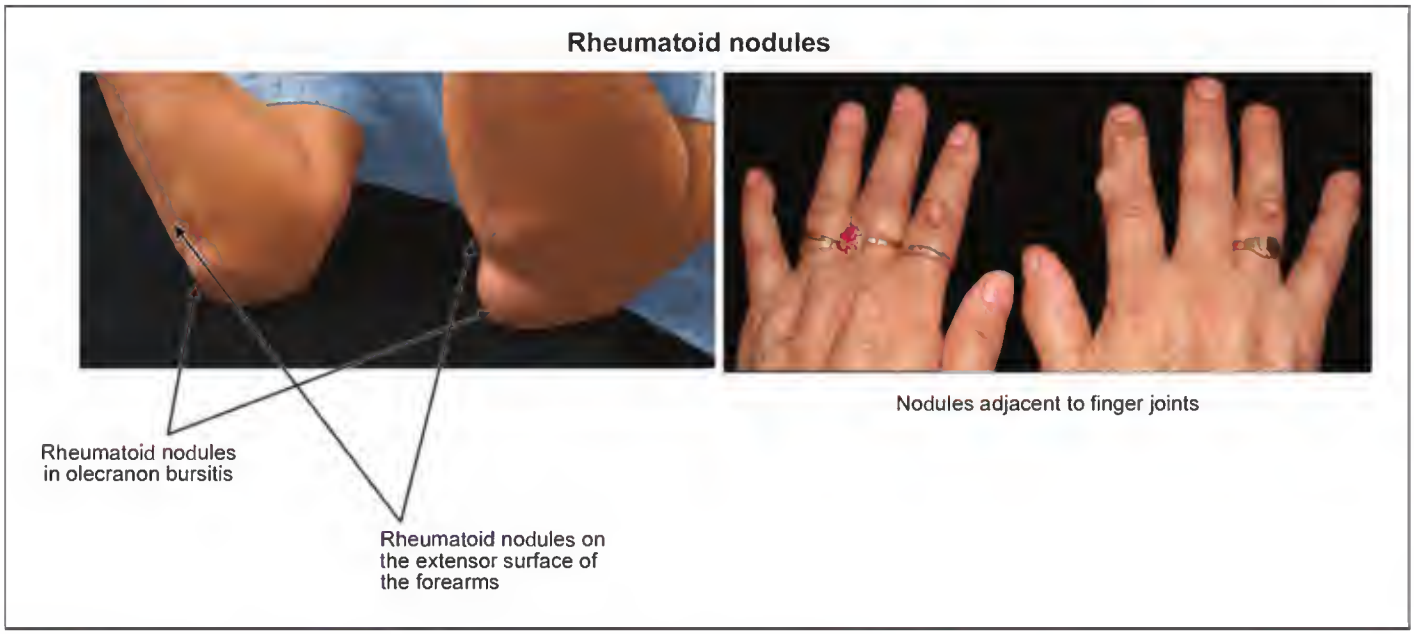

Figure 12: Rheumatoid nodules: on olecranon processes, forearms, adjacent to small finger joints.

complications of RA. In episcleritis, the eye becomes red and, in contrast to conjunctivitis, results in no discharge other than tearing in response to the gritty discomfort. Scleritis causes severe ocular pain and a dark red discolouration. No discharge is present. When severe, scleritis can cause resorption of the sclera down to the uveal layer, a complication called *scleromalacia perforans* that may cause vision loss.

Skin

There is no specific lesion of RA. The so-called 'senile' purpura resulting from skin atrophy and capillary fragility in patients inappropriately treated with long-term glucocorticoids is common. Palmer erythema and Raynaud's phenomenon may be seen. RA vasculitis usually manifests with nail fold infarcts or palpable purpura, most commonly seen on the lower leg. A severe form of vasculitis is a deep, erosive, ulcerated scarring lesion seen on the lower legs called pyoderma gangrenosum (**Figure 13**). It is indicative of severe disease that has not been well controlled. Severe systemic vasculitis, a dreaded complication of RA, is rarely seen now mainly because of early and effective treatment.

Lung

Pleuritis is the most common manifestation but in the majority it is subclinical. Interstitial pneumonia and fibrosis of non-specific class is more common in RA (as against scleroderma where the usual type interstitial lung disease is seen) (**Figure 14**). There is increasing dyspnoea associated with fine, diffuse, dry basal crepitations. Radiographs show a diffuse reticular (interstitial) or reticulonodular pattern in both lung fields often described as 'ground-glass' appearance; these can progress to a honeycomb appearance on plain radiographs and a characteristic lattice network seen on high-resolution CT scans. Less common but serious lung lesions in RA including nodules in the lung (**Figure 15**) (they may cavitate), bronchiolitis obliterans with organising pneumonia disease, arteritis with pulmonary hypertension and a rare small airways disease. Another important consideration is that methotrexate (MTX) and leflunomide (LEF), important drugs for treatment of RA, may also cause lung disease that may be difficult to distinguish from those caused by the disease itself. As a practical rule lung disease due to active RA that has been suboptimally treated is much more common than drug induced

Figure 13: Pyoderma gangrenosum on the lower leg.

Figure 14: Interstitial lung disease in RA.

Figure 15: Rheumatoid nodule in the lungs.

lung complications. Endogenous tuberculosis flare may occur after treatment with TNF-α inhibitors.

Haematological manifestations

Anaemia is common in RA. It is multifactorial and due to anaemia of chronic disease, iron deficiency due to gastrointestinal bleeding from indolent ulcers mostly caused by chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs), and superimposed B12 and folate deficiency. Serum ferritin concentration is much higher in anaemia of chronic disease than is found in isolated iron deficiency. Thrombocytosis as a result of systemic inflammation is also common in RA. Similarly, there could be some degree of polymorphonuclear leucocytosis.

Other organs

Rapid wasting of muscle proximal to the affected joints with weakness is common in RA. Neurologic involvement may take the form of entrapment neuropathies (carpal and tarsal tunnel syndrome), cervical myelopathy due to cervical spine subluxation and mononeuritis multiplex due to small vessel vasculitis. Renal disease in RA is rare. But drugs used in its treatment may affect kidney, NSAIDs being the most common culprit. Secondary amyloidosis of AA variety seen in long standing RA may cause nephrotic syndrome. Subtle subclinical heart involvement is not uncommon and includes pericarditis (rarely may cause symptomatic pericardial effusion or, even tamponade), myocarditis, endocarditis, valvular disease and conduction defects. Much more important, however, is systemic inflammation-related premature atherosclerosis leading to coronary artery disease and myocardial infarction in young.

Other clinical problems

Osteopoenia and osteoporosis is common and may lead to increased fracture risk. Risk of infection is also increased by approximately 1.5 to 2 times of the matched normal controls. Cancer risk, especially haematological malignancies, is 2 to 3 times higher in RA that is not related to its treatment.

Unusual Patterns or RA Variants

These include 'elderly-onset-RA' or EORA and *arthritis robustus (details available in the web version)*.

Syndrome of Early Undifferentiated Polyarthritis

If the duration of symptoms is less than 6 weeks, RA cannot be diagnosed with certainty. 30% to 40% of such patients may go in spontaneous remission never evolving into RA. Therefore, it has been called *undifferentiated polyarthritis syndrome* (UPS). ACR defines three categories of RA disease duration: early disease (<6 months), intermediate duration (6 to 24 months), and longer duration (>24 months, late RA). Early disease has been further subdivided by disease duration of <3 months (very early RA, VERA) or 3 to 6 months (late early RA, LERA).

Prognostic Factors and Mortality

Disease duration, number of affected joints, functional status, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level, degree of anaemia and presence of erosions at the time of first presentation and the presence of SE genes, correlate with severe aggressive disease. American College of Rheumatology recommends functional status (M-HAQ), presence or absence of extra-articular manifestations (rheumatoid nodules, sicca symptoms, vasculitis, lung disease); rheumatoid factor (RF) in significant titres; anti-citrullinated peptide antibody (ACPA) in significant titres; and bony erosions (on radiology) as determinants in treatment decision-making.

Life-expectancy is shortened among patients with RA than in the general population by 15% to 20% from the date of onset of illness, and lifespan is shortened by about 10 years in untreated RA. About 40% of the excess deaths were due to cardiovascular causes, other causes being infection, malignancy, and complications of the disease including increasing lung involvement, vasculitis, and other diverse causes.

Differential Diagnosis

Persistent inflammatory polyarthritis of RA pattern is seen a large number of other diseases. They are called 'mimics of RA'. The common ones include psoriatic arthritis, spondyloarthritis, reactive arthritis, systemic connective tissue diseases, systemic vasculitides, crystal-deposition arthritides, inflammatory-bowel disease related arthritis, sarcoidosis-related arthritis and several uncommon and rare conditions like Behcet's disease, relapsing polychondritis, multicentric reticulohistiocytosis, periodic syndromes, adult-onset Still's disease, relapsing seronegative symmetric synovitis with pitting oedema (RS3PE), Lyme disease, primary amyloidosis, joint symptoms related to hypothyroidism

and several other endocrinal diseases, hyperlipoproteinaemia-related joint disease. Certain noninflammatory joint diseases may be confused with RA, e.g. primary nodular osteoarthritis, joint pains in haemoglobinopathies. Psychogenic problems (e.g. fibromyalgia) may be confused with RA by inexperienced physicians.

LABORATORY INVESTIGATIONS

Routine Investigations

Routine laboratory tests at baseline are important for: (1) assessing the degree of systemic inflammation; (2) confounding factors (age, co-morbidities) requiring modification in management plan; (3) organ specific toxicities from prior drug use.

Systemic inflammation is gauged with ESR (Westergren method) and CRP levels in the blood. Systemic inflammation depresses albumin synthesis by liver causing hypoalbuminaemia. A reversal in albumin/globulin ratio is a common finding in active RA. Serum alkaline phosphatase (ALP) being an acute-phase reactant, is mild to moderately elevated in active RA.

Additional routine baseline studies should include liver enzymes, renal parameters, blood glucose and routine urine examination. These are important because certain drugs used in RA are hepatically cleared (NSAIDs, MTX, LEF). Also, drug dosages need to be modified in the presence of compromised renal status (MTX).

Autoantibodies

In addition to the above routine investigations, two antibodies should be tested in patients suspected with RA. These are RFs and ACPA. RF can belong to any immunoglobulin class (IgM, IgG or IgA). However, RF of IgM class are routinely tested in clinical immunology laboratories. Approximately 70% of patients with clinically diagnosed RA have significant titres of RF and are classified as seropositive RA while the others are classified as seronegative RA. High level of RF has approximately a sensitivity of ~ 70% and specificity of ~ 80% for the diagnosis of RA and is predictive of aggressive erosive disease with more extra-articular features and poor prognosis. Seronegative RA is usually a milder disease. It is not uncommon that the so-called seronegative RA patients turn out to have one of the mimics of RA in the follow-up; the most common being psoriatic arthritis. Thus, only a small proportion of RA patients remain truly seronegative over time. A large number of other chronic inflammatory conditions (systemic inflammatory rheumatic diseases including Sjögren's syndrome, SLE, and other connective tissue diseases, systemic vasculitides; sarcoidosis, chronic autoimmune hepatitis, primary biliary cirrhosis, others) and most chronic infections (tuberculosis, leprosy, bacterial endocarditis, hepatitis C, many others) may have RF. Like RF, significant titres of ACPA also predict aggressive, erosive disease with extra-articular features and poor prognosis. The sensitivity of significant titres of ACPA for RA is similar to RF (~ 70%) but specificity is much higher (~ 95%). ACPA is present in one-third patients who are negative RF at presentation.

It is now well established that ACPA and RF appear at least a decade before (the former appearing somewhat earlier) the onset of articular symptoms that evolve over time into RA (**Figure 2**). Antinuclear antibody (ANA) is another antibody present in approximately 20% to 30% of patients with RA, occasionally with high titres, but normal or increased serum complement levels (C3, C4) distinguish them from SLE where these are generally low. Occasionally, such patients may have true overlap of RA with SLE, often called rupus or rhupus.

Synovial fluid analysis

Examination of synovial fluid is not necessary for the diagnosis RA unless sepsis is suspected in any joint (out-of-proportion persistent swelling in an otherwise well controlled RA).

Imaging

Imaging plays an important role in the diagnosis as well as in the assessment of disease progression. Joints in the hands-wrists and, feet have smaller bones and thinner cartilage than the larger joints. Therefore, early radiographic changes are better seen in them and are recommended radiographs at the baseline and for the periodic assessment of joint disease in the follow-up. The earliest abnormality is periarticular osteopoenia, which is nonspecific and variable (**Figure 16**). With uncontrolled disease more characteristic changes of cartilage loss (joint space narrowing) and bony erosions appear by 6 to 12 months (**Figure 17**) and keep accumulating over time. Magnetic resonance imaging (MRI) and ultrasonic joint examination are more sensitive for detecting joint changes including synovial hypertrophy, joint effusion, tendon and ligament disease, erosions and rupture of joint cysts (e.g. Baker's cyst) than routine radiographs. They could be useful in early arthritis when clinical examination and standard radiographs may be unhelpful.

Figure 16: Periarticular osteopoenia (area shown with brackets).

TREATMENT AND ASSESSMENT

Approach to treatment of RA requires a team approach comprising of a physician-rheumatologist along with orthopaedic surgeon, specialist nurses, clinical assistants, physiatrists, counsellors and educators, and the supporting secretarial staff trained in the use of electronic medical records. Patient education is the key to this end. Psychosocial support to spouse and family is another important component of effective management. Socioeconomic factors need to be discussed with the patient and the family members at the outset. Health economics plays a key role in decision-making

Figure 17: Typical changes of RA on radiology with loss of joint space and erosions in most joints, and complete disorganisation of the wrist joints.

in drug treatment since most patients do not have health insurance or any kind of medical coverage in India.

Disease Assessment

Objective assessment at the baseline and at each of the follow-up visits is mandatory. The importance of objectified assessment can be better understood again with the examples of diabetes mellitus and hypertension where blood glucose/glycosylated haemoglobin levels or blood pressure measurements are needed at each follow-up visit. Similarly, joint count is mandatory for satisfactory treatment of RA.

There are well-defined domains in RA that need object assessment in the follow-up at recommended intervals. These include determination of: (i) disease (inflammatory) activity; (ii) functional status and quality of life (QOL); (iii) degree of joint damage; (iv) extra-articular problems. The assessment of disease activity is drawn from a composite of patient's perception of overall (global) pain and general health status as affected by the disease, on a visual analogue scale (VAS) of 0 to 100; the duration of morning stiffness in minutes; number of tender and swollen joints (examined and counted by the physician or any trained clinical assistant), physician's global assessment (VAS 0 to 100) after a detail clinical evaluation; and the level of inflammatory biomarkers (ESR and CRP). Using these five parameters a composite index called DAS (disease activity score) or DAS28 (if 28 joints are assessed) is calculated using a mathematical formula. The results obtained (in exact numbers on scale of 0 to 10) are then used to classify patients as having 'high', 'moderate', or 'low' disease activity or, 'remission' as determined by already established cut-off values. A simplified disease activity index (SDAI) that does not require complicated mathematical calculations has been recently devised. Simple addition of the number of tender and swollen joints, physician's and patient's global assessment (converted to 0-10 VAS) and CRP values (mg/litre) gives a number that determines the disease status based upon pre-determined cut off values. Further simplification called clinical disease activity index (CDAI), does away even with CRP values. Simple addition of the remaining four parameters gives the exact number that determines the disease status based upon pre-determined cut off values. These 'instruments' to measure disease activity, at any given point, are now being widely used in daily routine clinical practice to guide treatment decisions.

Functional status assesses all the domains of daily living (self-care, routine functions of daily living, vocational activity, avocational activities) using a self-administered health assessment questionnaire (HAQ) that provides objectified disability index (HAQ-DI). Several authenticated versions including an Indian modification (with 12 questions covering these aspects, M-HAQ-DI), are available. Radiographic damage is assessed using van der Heijde modification of the Sharp score, discussed above (see 'radiology') carried out at the baseline and at every six-month interval.

Treatment

Several overreaching principles guide the present-day treatment of RA. First and foremost is the recognition that damage and disability accrues rapidly in the first few months to two years. A delay of even as little as 3-4 months in initiating appropriate treatment makes significant difference in the outcome over long periods. The second principle is that accurate objectified assessment of disease activity used as guide for titrating treatment leads to much improved outcome both in the short as well as long-term. The third principle is based upon a notable observation that the toxicity of disease modifying anti-rheumatic drugs (DMARDs; see below), especially the newer ones led by MTX was actually less than the so-called simple painkillers NSAIDs. Based upon these principles, the modern day treatment for RA includes early diagnosis and initiation of early, aggressive, intensive, effective treatment with DMARDs to suppress inflammation continuously as ensured by periodic objectified assessment of disease activity targeting 'low-disease activity' or 'remission' all through a patient's life-time. **Table 3** gives the basic principles of modern-day treatment of RA namely, 'the tight disease control strategy'.

Table 3: Basic Principles of Modern-Day Treatment of RA: 'The Tight Disease Control Strategy' Based on Objectified Assessment of Disease Activity as a Guide for Response-Driven Targeted Treatment for Improved Outcome

Early diagnosis
The disease progresses rapidly; damage and disability accrues rapidly in the first few months to 2 years; A delay of even as little as 3-4 months in initiating appropriate treatment makes significant difference in the outcome over long periods.
Accurate objectified assessment of disease activity at base-line and at frequent intervals in the follow-up for titrating treatment.
Used as a guide for *response-driven targeted treatment* that has been shown to lead to much improved outcome both in the short as well as long term.
Aggressive treatments with DMARDs as monotherapy or in combinations, in 'step-up';'step-down' or 'saw-tooth' strategy:
Now there is proof that DMARDs are less toxic than NSAIDs, early aggressive use with MTX as the 'anchor drug'; improves both long- and short-term outcome, prevents damage and disease complications.
Judicious use of glucocorticoids.
Improved understanding of glucocorticoid actions and effective strategies for their use in RA minimising adverse effects, improves treatment outcome.

Drugs

There are three main categories of drugs used in the treatment of RA, namely NSAIDs; standard DMARDs and biological DMARDs; and glucocorticoids.

Nonsteroidal anti-inflammatory drugs (NSAIDs)

These symptom-controlling compounds provide symptomatic relief from pain and inflammation. NSAIDs belonging to different classes are available namely; salicylates (aspirin); derivatives of acetic acid (indomethacin, etodolac), anthranilic acid (mefenamic acid), sulfonanilides (nimuselide), heteroaryl acetic acid (diclophenac), arylpropionic acid (ibuprofen, naproxen, ketoprofen), and enolic acid (piroxicam, meloxicam). These drugs belong to the standard non-selective NSAIDs group. The other category of selective COX-2 inhibitor group include the coxibs (celecoxib, etoricoxib). There is wide variability in patient preferences for these drugs and patients are allowed to choose agents of their choice, the so-called 'menu-approach'. Adverse effects of NSAIDs include gastrointestinal (abdominal pain, erosions/ulcers, bleeding and perforation in small and large bowl; nausea, anaemia), renal (salt-water retention, oedema, worsening renal function, hyperkalaemia), liver (transient rise of liver enzymes, cholestasis, acute liver injury), central nervous system (headache, dizziness, confusion, lowered seizure threshold), platelets (inhibit platelet activation, bruising, haemorrhage), cardiovascular (premature closure of ductus arteriosus, heart failure worsening, myocardial infarction, haemorrhagic stroke), and hypersensitivity (angioedema, asthma, hypotension, shock). A combination of NSAIDs should not be used as the pharmacological action of all NSAIDs/Coxibs is similar. Combinations enhance toxicity not efficacy. An important therapeutic principle of their use is to give a larger dose at bedtime that is more effective in controlling early morning symptoms, so troublesome in RA patients. Another important principle of their use is that if a patient requires their continuous use due to incomplete pain control, the cause of pain must be carefully evaluated. Persistent pain usually implies poor disease control that is definitely not an indication for continuous use of NSAIDs/Coxibs. Rather, it would require a reassessment of the choice and the dose of DMARDs (see below), the prescribed combination(s) and the patient compliance. Another reason for persistent pain despite good disease control could be mechanical in origin due to structural joint damage where a surgical intervention, if warranted, may permanently relieve the pain.

DISEASE MODIFYING ANTI-RHEUMATIC DRUGS (DMARDs)

Standard DMARDs (Table 4)

These are a diverse group of synthetic small molecules empirically shown to reduce the signs and symptoms of RA but, have additionally found to be effective in slowing down disease activity and halt disease progression and damage. Of a large number of these drugs, presently only four of them are widely used: MTX, sulphasalazine (SSZ), LEF, and hydroxychloroquine (HCQ). The other two, namely cyclosporine and minocycline are also used but sparingly. Older DMARDs include organic gold, D-penicillamine, and chloroquine. Other DMARDs include cytotoxic drugs, e.g. azathioprine, cyclophosphamide and others. But due to unfavourable safety profile older DMARDs and cytotoxic drugs are rarely used now.

Hydroxychloroquine (HCQ)

It belongs to the group of anti-malarial drugs. Being much less toxic than its older cousin chloroquine, HCQ is a popular drug for the treatment of RA. It is among the safest DMARDs with mild action, best suited for patients with mild disease. Approximately 40% of the patients get measurable benefit. It is also very popular as an adjunct drug for use in DMARD-combinations for patients with more aggressive disease. At the recommended dose of 400 mg daily ($\leq$ 6.5 mg/kg body weight) it has little adverse effects except darkening of the exposed skin that may be reduced with proper clothing, sun-screen lotions and avoiding direct sun exposure. Used at this dose, true retinopathy has become a rarity. However, if given for prolonged periods (>10 years) it would be prudent to get proper retinal examination done for HCQ retinal toxicity. Other reported adverse effects include abdominal discomfort, nausea, lose motions, skin rash, tinnitus, headache and myopathy. It crosses placenta, therefore, with risk of foetal abnormalities.

Sulphasalazine (SSZ)

It was the first drug to be specifically designed by Svartz (1942) for the treatment of RA. Approximately 45% of patients would have beneficial effect at the end of 6 months. It is a popular drug for mild-to-moderate early disease and, like HCQ is the most popular DMARD to be used in combination with MTX and HCQ therapy. It is generally well tolerated but, gastrointestinal disturbance and intolerance, allergic skin rash, reversible reduction in sperm count are not uncommon. Less commonly

Table 4: Disease Modifying Anti-Rheumatic Drugs (DMARDs): Standard DMARDs and Biological DMARDs

Synthetic small molecules empirically found to be effective in the treatment of RA (Standard DMARDs)			Mechanism-based molecules produced biotechnologically for targeted modification of biological response (Biological DMARDs)
DMARDs presently used widely	**DMARDs presently used sparingly**	**DMARDs not widely used now**	**Inhibitors of tumour necrosis factor-α (iTNF-α):** Infliximab, etanercept, adalimumab*, certolizumab pegol*
Low-dose methotrexate (LD-MTX)	Minocycline Cyclosporine	Organic-gold compounds D-Penicillamine	**B-cell depletion therapies** **Rituximab**
Sulphasalazine	Others: tacrolimus	Chloroquine	**Others:** Tocilizumab (inhibitor of IL-6), abatacept (co-stimulation blocker), large number of other molecules in the 'pipeline'

Leflunomide			

**Not released in India at the time of writing.*

cytopoenias and liver function abnormalities may be seen. A rare manifestation is drug-induced lupus.

Methotrexate (MTX)

It was developed several decades ago as an anti-cancer drug that works as a potent inhibitor of dihydrofolate reductase (DHFR), a critical enzyme in folate metabolism. The dose of MTX required for its cytotoxic-antiproliferative action in the treatment of malignancies is, however, high; usually >1gm/m^2 (average person measures 1.73 m^2). Therefore, therapeutically, the MTX dose required to treat malignancies has been designated *'HD-MTX'*. It is of note that the rheumatologists use several folds less MTX dose than that used in oncology; mostly in the range of 7.5 to 15 mg once weekly. Only in recent days dose in the range of up to 15 mg/m^2 or 25 mg/wk (maximum of 30 mg/wk) has been recommended. The therapeutic dose of MTX used is rheumatological conditions is, therefore, called LD-MTX. It would appear that HD-MTX and LD-MTX are, for all practical purposes, two different drugs with different modes of action and different indications of use in clinical medicine (details on web version).

LD-MTX in RA

LD-MTX is now considered the 'anchor drug' among DMARDs. The beneficial effects become visible within weeks. MTX is used in RA as a monotherapy as well as the cornerstone in any DMARD combination, including those with biologicals. It has a convenient weekly dose schedule; it is inexpensive and better tolerated than most other DMARDs with high 'retention rate' over long periods of time. LD-MTX can be administered orally or by subcutaneous injections. Oral weekly dosing is convenient but, above 15 mg/week dose, a switch over to subcutaneous route improves gastrointestinal tolerability and bioavailability. Conventionally, the initial dose is 7.5 mg weekly that is escalated every two weeks to a maximum of up to 30 mg weekly dose to achieve maximum disease control. More recently, it has been recommended that in patients with no risk factors (see below) LD-MTX treatment could be initiated at the dose of 15 mg/week orally, escalating with 5 mg/month to a maximum of 25-30 mg/week with a switch to subcutaneous administration in the case of an insufficient response. However, patients with very active polyarticular disease and markers of bad prognosis will benefit from starting with parenteral administration. The dose may be successfully reduced to once in two weeks in patients with stable remission for a long-time. LD-MTX has also been shown to reduce radiological progression of disease.

Common Adverse Effects and Monitoring of LD-MTX Treatment

Toxicity monitoring is simple and inexpensive and only includes blood counts, liver enzymes (AST, ALT), and renal status (serum creatinine). Commonly seen adverse effects, albeit minimal, include gastrointestinal intolerance, stomatitis, hair loss and liver function abnormalities. At the recommended doses bone marrow suppression is rare. Folic acid or folinic acid supplementation reduces the frequency of liver function test abnormalities, stomatitis and marrow suppression. Folic acid supplementation is at the dose of 1 mg daily or 5 mg weekly on the next day of the MTX dose. Switching to subcutaneous injections is another way of offsetting GI intolerance. Mucositis can be easily controlled with folinic acid supplementation (usually 50% of the MTX dose) given 12 hours after the LD-MTX dose. MTX is teratogenic, therefore, needs to be discontinued for at least 10-12 weeks before the patient tries for pregnancy. Rare adverse effects (~1%) include interstitial pulmonary inflammation and fibrosis that would necessitate discontinuation of the drug. However, the earlier debate related to MTX-induced lung and liver fibrosis has slowly died down as this does not appear to be a great risk. Most vaccinations work well and not suppressed with LD- MTX.

Leflunomide (LEF)

It suppresses the *de novo* synthesis of pyrimidine (uridine and cytidine) nucleotides by inhibiting dihydroorotate dehydrogenase. It is given orally once a day at the dose of 10 or 20 mg. Adverse effects include diarrhoea, liver toxicity (transaminitis), leukopenia and potential to raise blood pressure. It is potentially teratogenic and normally should not be prescribed in women in reproductive age unless strict contraception is ensured.

Table 5 gives details of commonly used standard DMARDs.

Biological DMARDs

These are genetically engineered biotechnologically produced version of natural molecules that specifically target pathogenic mediators of joint inflammation and damage. There are two main categories of biologicals namely monoclonal antibodies (suffix 'mab') and, fusion proteins (suffix 'cept'). They are highly effective in controlling disease activity, and halting/reversing disease progression and damage (**Table 5**). The major drawback is cost.

Glucocorticoids (GC)

Besides their anti-inflammatory action they have been shown to retard disease progression and joint damage in RA. Unfortunately, because of serious systemic long-term adverse effects GC use in RA remains limited to only a few situations: (i) Depot-preparations for intra-articular or intra-lesional administrations to control localised disease flares such as in a single (or a few) joint(s) or para-articular lesions such as tenosynovitis, carpal tunnel syndrome others. The commonly used preparations are depot-methylprednisolone, depot-triamcinolone-acetonide and depot-triamcinolone-hexacetonide (the last one not available in South-East Asia); (ii) Depot-methylprednisolone given as intramuscular injections at weekly intervals for a few weeks at the initiation of DMARD treatment as 'bridge-therapy', to control inflammation and pain during the period it takes for slow-acting DMARDs to start their action; (iii) Large-dose intravenous bolus given on 2 or 3 consecutive days for 'debulking' of severe disease at the initiation of treatment or uncontrolled disease flare during the follow-up; (iv) As one of the drugs in a step-down combination-DMARD strategy with a moderate dose that is tapered off over the next several weeks; (v) For treating some of the more serious complications of RA, e.g. vasculitis, eye and pulmonary involvement, serositis; (vi) To prevent nausea, vomiting and gastrointestinal intolerance often seen with MTX dose of 20 mg/week or more. A small to moderate dose of GC given about 15-30 minutes before the MTX dose once-a-week may relieve this problem. Prolonged continuous daily use of GC in RA is not recommended especially in our country where metabolic syndrome is a major problem in the population. An important

Table 5: Standard and Biological DMARDs for the Treatment of RA: Dose/Route of Administration, Clinically Relevant Adverse Effects, Screening and Monitoring

Standard DMARD	Route/ Schedule	Clinically Important Adverse Effects	Screening	Monitoring
Low-dose methotrexate	Oral/subcutaneous weekly	GI intolerance, mucositis, transient transaminitis	Renal and liver status, blood counts, hepatitis B and C	Complete blood counts, liver enzymes, serum creatinine 2-3 monthly.
Hydroxychloroquine	Daily oral dose	GI intolerance, skin rash, skin hyperpigmentation Prolonged therapy with dose >6 mg/kg may rarely cause retinopathy	In patients > 50 years of age taking drug for several years, yearly eye examination for retinal toxicity	—
Sulphasalazine	Daily in divided dose	GI intolerance, skin rash, rarely granulocytopaenia	Complete blood count, liver status and G6PD deficiency	Complete blood count, liver enzymes 2-3 monthly
Leflunomide	Single daily dose	Diarrhoea, skin rash, alopecia, transaminitis, granulocytopaenia	Complete blood count, liver enzymes, renal function, hepatitis B and C	Complete blood count, liver enzymes, serum creatinine, 2-3 monthly
Biological DMARD	**Dose/route**	**Clinically important adverse effects**	**Screening**	**Monitoring**
Infliximab	IV infusion over 4-6 hours, usually 3 monthly infusions	Flare of latent tuberculosis, other infections, autoimmune phenomenon, psoriatic lesions, increased chances of malignancy?	For latent tuberculosis, infections	For tuberculosis, infections
Etanercept	50 mg weekly subcutaneous injections	Local injection reactions; infections; flare of latent tuberculosis	-do-	-do-
Rituximab	IV infusion cycles of 1 gm slow IV infusion × 2 at 15 day interval; to be repeated 6 monthly	Allergic reactions during infusions, infections, multifocal leucoencephalopathy	Infections, hepatitis B and C screening	Infections
Abatacept	1 gm as slow IV infusion every 15 days × 3; Subsequent doses 4 weekly	Infections	-do-	-do-
Tocilizumab	8 mg/kg body weight, given as slow IV infusion, every month	Infections, deterioration in lipid profile, especially blood triglyceride levels	-do-, lipid profile	-do-, lipid profile

point to remember is that, when used over prolonged periods, there is no safe dose of GC. Even at very low doses (≤7.5 mg per day) adverse effects, especially osteoporosis and cataract, do occur. Several trials in RA have shown that when given in combination with DMARDs even for a short period at the treatment initiation, the beneficial effects persist during several years in the follow-up. Therefore, the best approach is to be reasonable and use GC judiciously, always combined with effective doses of DMARDs and never prescribing it as a 'stand-alone' drug for treating RA. The most commonly used oral preparation of GC is prednisolone. Methylprednisolone oral tablets are also available but more expensive.

TREATMENT STRATEGY AND RECOMMENDATIONS

The treatment goal is to achieve rapid and lasting *low-disease activity status* or *remission*. The key step towards achieving this goal is to initiate DMARD treatment as soon as RA is diagnosed, definitely within the first 3 to 6 months. It is now the standard of care for RA. The actual treatment strategy best suited for a particular patient is then guided by the patient and the disease characteristics: (a) Disease *duration* (early <6 months, intermediate 6 to 24 months, and late >24 months); (b) Disease *severity* (low disease activity, moderate-high disease activity based on DAS28 values or CDAI, SDAI); (c) *Features of poor prognosis* (functional status as measured by M-HAQ-DI or its variations) due to large number of swollen, tender joints (usually >20 active joints); extra-articular disease (e.g. presence of rheumatoid nodules, secondary Sjögren's syndrome, RA vasculitis, Felty's syndrome, and RA lung disease); high ESR and high levels of CRP; high titres of RF and ACPA; bone oedema or erosions on imaging; and presence of certain genetic markers (HLA-DR4 SE, other single nucleotide polymorphism). Therapeutic armamentarium consists of standard and biological DMARDs,

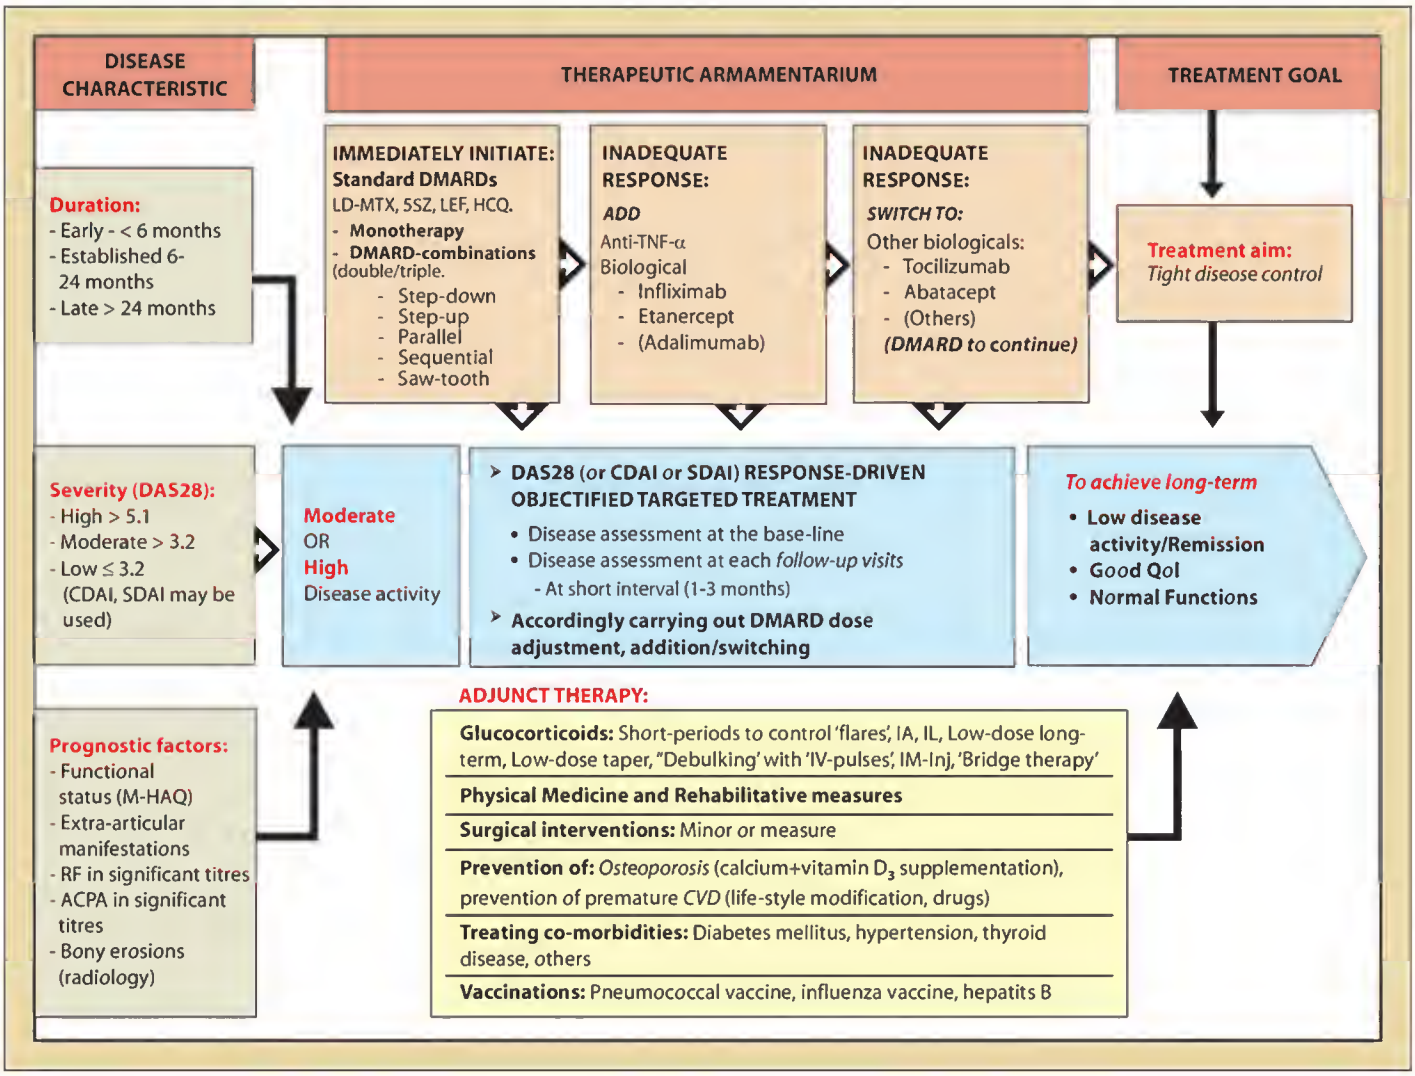

Figure 18: An overview of treatment strategy for RA.

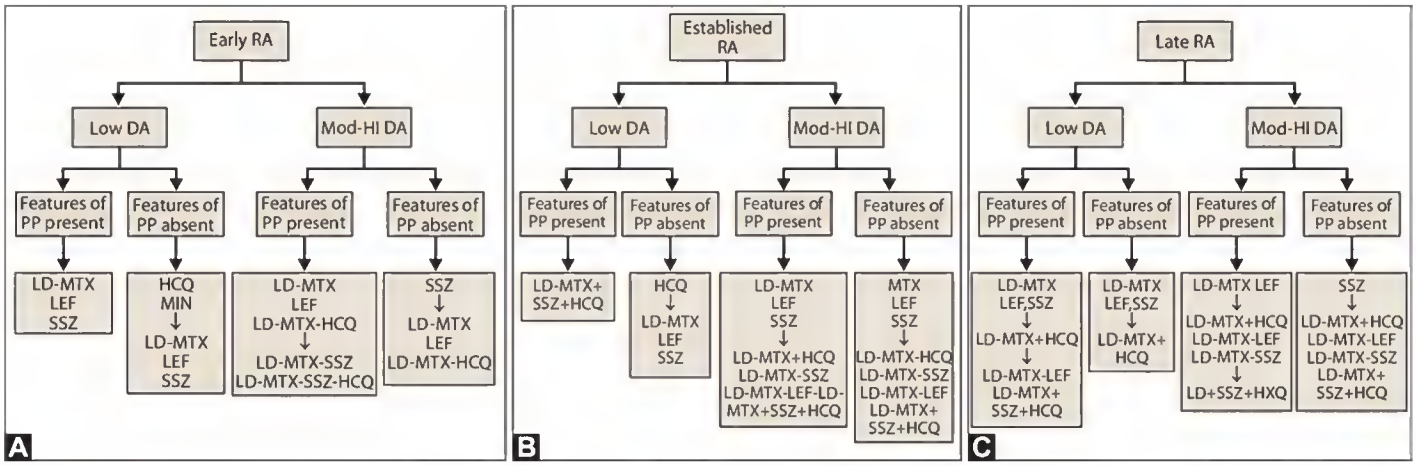
judicious use of GC and adjunct and supportive treatment. An overview of treatment strategy for RA is given in **Figure 18.**

Use of Standard (Non-Biological) DMARDs

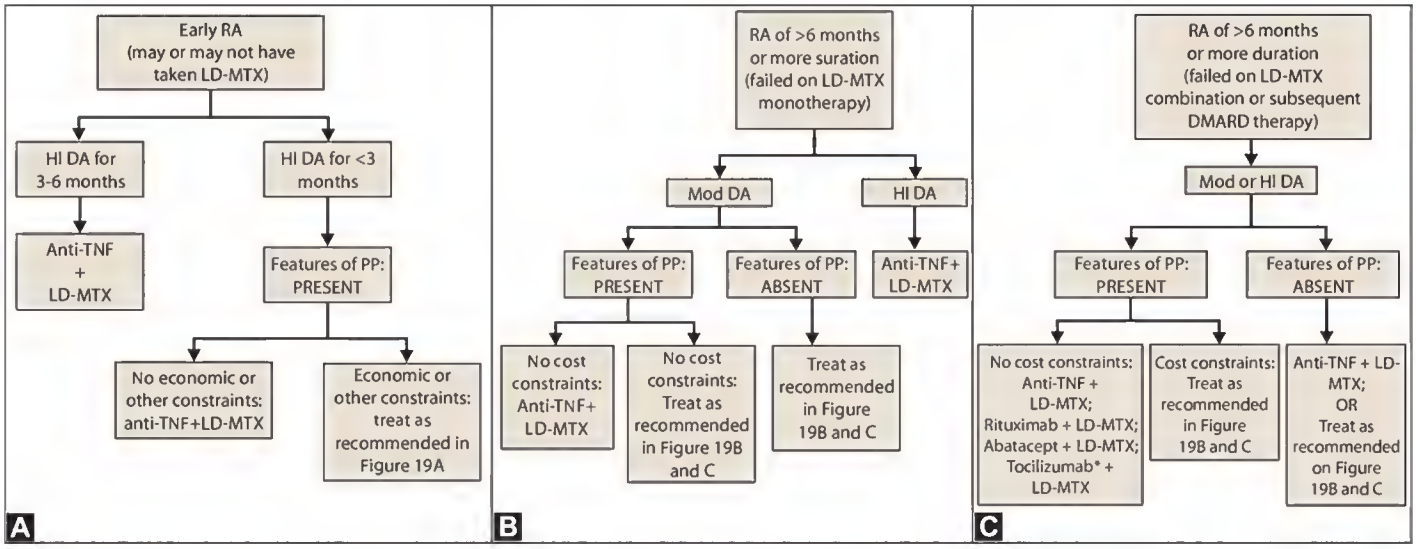


Based upon the variables mentioned above patients are treated according to the algorithm given in **Figures 19A to C.** DMARDs are used as monotherapy, as duel-DMARD combination or as triple-DMARD combination therapy. Often these are combined with systemic GC mainly at the initiation of treatment as 'bridge' therapy or for 'debulking' or during disease flares (see under 'glucocorticoids'-above). As a general rule, adequate doses of standard DMARDs should be given for adequate periods of time to achieve satisfactory response. Only if the satisfactory response is not achieved after such a trial of standard DMARDs, biologicals are considered as a therapeutic option. Traditionally 6 to 12 weeks of maximally tolerated doses are given to evaluate the efficacy of a certain DMARD/DMARD combinations. If low-disease activity state or remission is not achieved by the end of that period it could be considered an 'unsatisfactory response' and the treatment is modified accordingly.

Use of Biological DMARDs

At the time of writing the drugs approved and available in India included specific inhibitors of TNF-α namely the chimeric monoclonal antibody infliximab (fully humanised adalimumab not yet released in India) and fusion protein etanercept. Monoclonal antibody against CD20 positive B cells called rituximab, co-stimulation blocking fusion protein CTLA4-Ig called abatacept, and monoclonal antibody against IL-6 called tocilizumab are also available. Present day recommendation of these highly expensive drugs is in patients who do not achieve satisfactory disease control with standard DMARDs within a reasonable period of time. Under certain circumstances they could also be recommended in patients at a much earlier stage if several features of poor prognosis are present and the cost and insurance coverage is not a limiting factor. The algorithm for the use of biological DMARDs in RA is given in **Figures 20A to C.**

Treatment of Complications of RA and Co-Morbidities



Treatment of RA requires much more than just the stringent control of disease activity. Thus, sicca features require appropriate moisturising eye drops, control of eye infections and some drugs (e.g. pilocarpine) to enhance tear production. Frequent sips of water help preventing complications in the mouth-mucosal infections, sores; stringent oral hygiene is necessary to prevent dental problems in such patients. GC and cytotoxic drugs may be required for interstitial lung. Commonly seen co-morbidities in RA include diabetes

Figures 19A to C: Algorithm for the treatment of RA with standard non-biological disease modifying drugs (DMARDs).

Early RA = RA < 6 months durotion; Low DA= low diseose octivity as defined by DAS28 volue < 3.2; Mod-HI DA = Moderote/high diseose octivity defined by DAS28 value ≥ 3.2; Feotures of PP = Feotures of poor prognosis [include functional limitotion (defined by using ony stondord measurement scoles, e.g. 'modified-Health Assessment Questionnoire' or volidoted voriotions of this scale), extro-orticulor monifestations (e.g. presence of rheumatoid nodules, secondory Sjögren's syndrome, RA vasculitis, Felty's syndrome, ond RA lung disease), rheumotoid factor positivity (in significant titres), positive onti-cyclic citrullinoted peptide antibodies (in significant titres), or bony erosions by rodiography]; LD-MTX = low-dose methotrexote (up to 30 mg/week, the dose used in rheumotology in contrast to high-dose methotrexote used in oncology proctice); LEF = leflunomide; SSZ = sulphasalozine; HCQ = hydroxychloroquine; '+' sign indicotes recommended use of these drugs in combinotion. Estoblished RA = diseose durotion of 6 to 24 months; the sign '↓' indicates 'If foilure to respond'; Late RA = diseose duration > 2 yeors.

mellitus, hyperlipidaemia, hypertension, cardiovascular disease and thyroid disease. These need appropriate treatment.

The Role of Physical Medicine and Surgery in the Treatment of RA

These include physical therapy exercises, use of different physical modalities for pain relief, help in maintaining muscle mass, full range of joint movements and preventing deformities. Additionally, the use of different appliances for simplifying and assisting in daily chores are available. Surgeons specialising in soft-tissue surgery and bone-and-joint surgeons play very important role in the management of RA especially in advanced disease.

24.7 Spondarthritides

Milind Y Nadkar

Spondarthritides or spondyloarthritides (SpA) are a family of related inflammatory diseases which include ankylosing spondylitis (AS), reactive arthritis (ReA), psoriatic arthritis and spondylitis, enteropathic arthritis and spondylitis, juvenile-onset spondyloarthritis, and undifferentiated spondyloarthritis (**Table 1**). These disorders are also referred as seronegative spondyloarthropathy (SSA) as these are negative for rheumatoid factor (RF).

Table 1: Spondyloarthropathies

Ankylosing spondylitis
Reiter's syndrome or reactive arthritis
Arthropathy of inflammatory bowel disease (Crohn's disease, ulcerative colitis)
Psoriatic arthritis
Undifferentiated spondyloarthropathies
Juvenile chronic arthritis and juvenile-onset ankylosing spondylitis

These disorders share certain clinical features and genetic associations: predilection for male sex, asymmetric lower limb large joint arthritis, sacroiliitis, enthesitis (inflammation of the ligamentous attachments to the bones), uveitis, dactylitis, absence of rheumatoid factor and a strong association with human leucocyte antigen (HLA)-B27.

The European Spondyloarthropathy Study Group (ESSG) has provided classification criterion to have uniformity among patients (**Table 2**). The sensitivity and specificity of ESSG criteria is 87%. The comparison between different members in this group is given in **Table 3**.

Table 2: European Spondyloarthropathy Study Group Classification Criteria for Spondyloarthropathies

Inflammatory spinal pain
OR
Synovitis (asymmetric, predominantly in lower limbs)
AND
Any one of the following (sensitivity, 77%; specificity, 89%)
Positive family history
Psoriasis
Inflammatory bowel disease
Alternate buttock pain
Enthesopathy
Adding sacroiliitis (sensitivity, 86%; specificity, 87%)

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is an inflammatory condition. Predominant clinical feature of AS is inflammatory backache followed by stiffness of the spine. The diagnosis of AS in most clinical trials is based on the modified New York (1984) criteria (**Table 4**). In the past radiographic sacroiliitis was an important pre-requisite to diagnose AS. However, magnetic resonance imaging (MRI) has now made it possible to make an earlier diagnosis. This has been incorporated in the newly developed Assessment of Spondylo Arthritis International Society (ASAS) SpA criteria (**Table 5**).

Table 3: Features of Spondarthritides

Characteristics	AS	ReA/ USpA	PsA	IBD-Associated Arthritis
Age of onset (years)	<40	20 to 40	30 to 55	Young and middle-age
Type of onset	Insidious	Acute	Insidious	Insidious
Male: Female	5:1	1:1	Male predominant	1:1
Sacroiliitis or spondylitis	100%	<50%	<50%	<20%
Peripheral arthritis	40%	~90%	~90%	15 to 20%
HLA-B27 (whites)	90 to 95%	~75%	~85%	~50%
Eye involvement	30%	~50%	~20%	15%
Cardiac involvement	1 to 4%	5 to 10%	Rare	Rare
Skin or nail involvement	None	< 40%	~100%	10 to 15%
Role of infectious agents as triggers	Unknown	Yes	Unknown	Unknown

AS = Ankylosing spondylitis; ReA = Reactive arthritis; USpA = Undifferentiated spondyloarthropathies; PsA = Psoriatic arthritis; IBD = Inflammatory bowel disease; HLA-B27 = Human leucocyte antigen-B27.

Table 4: Modified New York (1984) Criteria

Criteria
Low back pain of at least 3 months' duration improved by exercise and not relieved by rest
Limitation of lumbar spine in sagittal and frontal planes
Chest expansion decreased relative to normal values for age and sex
Bilateral sacroiliitis grade 2 to 4
Unilateral sacroiliitis grade 3 or 4
Definite ankylosing spondylitis
Unilateral grade 3 or 4, or bilateral grade 2 to 4 sacroiliitis and any clinical criterion

Epidemiology

AS is present in 1% to 6% of adults inheriting HLA-B27, whereas the prevalence is 10% to 30% among HLA-B27+ adult first-degree relatives. In whites, the prevalence of AS is 0.5% to 1% and male to female ratio is 5:1. The HLA-B27 is found in 90% to 95% of patients. There are no Indian data on prevalence of AS. Positivity of HLA-B27 in studies from north and south India is 94% and 83%, respectively. High concordance rate in identical twins of 65% further emphasises the genetic role.

Pathogenesis

There is a persistent inflammation at the affected synovial joints and entheseal sites with increased mononuclear cell infiltrates. Participation of both macrophages and T cells in an inflammatory

process triggered by an yet undefined antigen presented by susceptible HLA molecules is believed to be fundamental to the pathogenic process. The strong association of HLA-B27 in all ethnic groups suggests a predominant role for this class I molecule. The HLA-B27 has 29 subtypes and B2704 and B2705 are susceptible and B2706 and B2709 are non-susceptible subtypes. Certain environmental microbial factors interplay with susceptible genes to trigger off the immune-mediated synovitis. However, the link between any particular microbe with AS is weak.

Table 5: Assessment of Spondyloarthritis International Society (ASAS) Criteria for Classification of Axial SpA

Sacroiliitis on Imaging plus ≥1 SpA Feature	OR	HLA-B27 Plus ≥ 2 Other SpA Features
In patients with >3 months back pain and age at onset <45 years		
SpA Features		**Sacroiliitis on Imaging**
Inflammatory back pain Arthritis Enthesitis (heel) Uveitis Dactylitis Psoriasis Crohn's/colitis Good response to NSAIDs family history for SpA HLA-B27 Elevated CRP		Active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA definite radiographic sacroiliitis according to modified New York criteria (1984)

The dramatic response of the disease to therapeutic blockade of tumour necrosis factor-α (TNF-α) indicates that this cytokine plays a central role in the immunopathogenesis of AS. The inflammed sacroiliac joint is infiltrated with CD4+ and CD8+ T-cells and macrophages and shows high levels of TNF-α.

Pathology

Common pathologic features of AS include synovitis, pannus formation, myxoid marrow, subchondral granulation tissue and marrow oedema, and enthesitis. In the spine, there is inflammatory granulation tissue at the junction of annulus fibrosus and vertebral bone. The outer annular fibres are eroded and eventually replaced by bone, which eventually forms a bony syndesmophyte, which then grows, ossifies and bridges the adjacent vertebral bodies. Ascending progression of this process leads to the typical 'bamboo spine' appearance.

Clinical Features

The average age of onset is 25 years and onset after the age of 40 to 45 years is very rare. About 15% of patients have onset of the disease in childhood. AS develops insidiously with chronic low back pain associated with early morning stiffness, which is the presenting feature in 85% of cases. The back pain is due to sacroiliitis and inflammation of the several entheseal sites where the spinal ligaments attach with the vertebral bodies. Patient complains of night pain and sleep disturbance. The inflammation of sacroiliac joint is felt as deep sacral pain, or buttock pain. Over the years inflammation progresses to ascend upwards with involvement of dorsal and cervical spine. With the involvement of dorsal spine, patient complains of chest pain and tightness of chest. The spinal inflammation results in restriction of spinal involvement, with difficulty in bending forward and looking over the shoulders, which are worse in the morning and somewhat relieved with physical activity.

Sacroiliac joint tenderness is elicited by direct palpation and compression of pelvis with patient lying on one side. Spinal restriction is tested by measuring the expansion of lumbar spine on full flexion called the Schober's test (two points one 10 cm above and 5 cm below the lumbosacral junction is marked in upright position and then the patient is asked to fully flex forward and the expansion is noted. It is considered abnormal if the expansion is less than 5 cm). Other useful measurements include finger-to-floor distance, lateral flexion of the spine, chest expansion and occiput to wall distance when patient standing erect against a wall.

Arthritis in the hips and shoulders occurs in 25% to 35% of patients, in many cases early in the disease course. If hip involvement has not occurred within 10 years of the disease onset, it is unlikely to get involved subsequently. An asymmetric arthritis of peripheral joints occurs in up to 30% of patients. Peripheral joint involvement is relatively common (up to 40%) in India.

Enthesitis is an important manifestation with pain and tenderness of tendo Achilles, plantar fascial insertion sites in the calcaneus bone, ligamentum patellae attachment at tibial spinous process, costochondral junction and tenderness over the spinous process insertion, anterior-posterior-superior iliac spine, iliac crest, etc.

In a severe untreated case with progressive spondylitis, the patient's posture undergoes characteristic changes, with obliterated lumbar lordosis, buttock atrophy, and accentuated thoracic kyphosis. A forward stoop of the neck and flexion contractures at the hips, compensated by flexion at the knees occurs.

The disease starts in adolescence and there is a mean delay of 9 to 10 years from the first symptoms to a definite diagnosis. Occasional patients, particularly in the older age group, present with predominantly constitutional symptoms. Severe spinal restriction (<3 cm of lumbar movement) occurs in up to 41% of patients and majority (81%) of these patients are severely restricted within 10 years of onset. Limitation of motion is usually out of proportion to the degree of bony ankylosis, which is due to muscle spasm secondary to pain and inflammation. Spinal progression is a function of disease duration. In patients with mild disease, life-span is comparable to that of general population. The causes of mortality are spinal fractures, cardiopulmonary involvement, complications of treatment, and accidents.

Extra-articular manifestations

The most common extra-articular manifestation is acute anterior uveitis occurring in 25% to 40% of patients. Attacks are typically unilateral, causing pain, photophobia, and increased lacrimation and tend to recur. Uveitis can occur before the onset of spondylitis.

Spinal osteoporosis frequently occurs in patients with long duration of the disease. Patients may develop atlanto-axial subluxation or *cauda equina* syndrome due to chronic adhesive arachnoiditis.

Aortitis may occur in AS leading to aortic regurgitation. Conduction disturbances may occur due to fibrosis in conduction tissues. Conduction disturbances may occur in up to 9% of patients after 30 years of the disease. Apical lung fibrosis (usually bilateral) occurs in 1% to 2% patients.

Asymptomatic enteric mucosal lesions have been detected in terminal ileum and proximal colon on colonoscopy studies in up to 60% of patients. On follow-up, 6% of these develop into inflammatory bowel disease. An increased incidence of immunoglobulin (Ig)A nephropathy has been reported in AS. Renal involvement may also be due to secondary amyloidosis.

Investigations

Mild normocytic normochromic anaemia is present in 15% of patients. Erythrocyte sedimentation rate and reactive protein are usually elevated in up to 75% of the patients with active AS. The HLA-B27 is present in approximately 90% of patients. Synovial fluid from peripheral joints in AS is non-specifically inflammatory.

The most important investigation is anterior-posterior plain radiograph of the pelvis with both hip joints (**Figures 1A and B**) and lateral view of the lumbar, dorsal and cervical spine. Bilateral sacroiliitis is the hallmark of ankylosing spondylitis. Changes in the lower-third of the joint is important and includes blurring of the joint margin, widening and narrowing, sclerosis on the ileal aspect of the joint and finally fusion. These can be graded as shown in **Table 6**. Subsequently the vertebrae are involved with shiny corners (Romanus lesion), squaring, syndesmophytes which are calcification of longitudinal ligaments which later on fuse with adjacent vertebra called as bridging syndesmophytes (**Figure 2**). In advanced cases when the entire spine is involved typical 'bamboo spine' appearance is seen (**Figure 3**). Computed tomography and MRI reveal sacroiliitis and hip arthritis (**Figures 4A and B**). On MRI, sacroiliitis can be revealed early in the course of the disease with underlying bone marrow oedema (**Figure 5**).

Table 6: Grading of Radiographic Sacroiliitis

Grade 0	=	Normal
Grade 1	=	Suspicious
Grade 2	=	Sclerosis, some erosions
Grade 3	=	Severe erosions, widening of the joint space, some ankylosis
Grade 4	=	Complete ankylosis

Differential Diagnosis

Presence of early morning stiffness and raised ESR or CRP differentiates AS from mechanical back pain. Diffuse idiopathic skeletal hyperostosis (DISH) can resemble AS both clinically and radiologically. In DISH the radiological abnormalities involve four contiguous vertebral bodies where flowing osteophytes bridge adjacent vertebrae in the absence of degenerative disc changes and sacroiliac joint changes. It is uncommon before the age of 45 years and is associated with normal ESR/CRP.

Management

Management is aimed at controlling inflammation and increasing mobility. All patients should be counselled and emphasised on exercise to mobilise the stiff spine. Back extension exercises should be encouraged. Swimming is particularly a helpful exercise that ensures adequate spinal movement.

Figures 1A and B: Radiograph of pelvis with both hips showing: (A) Bilateral sacroiliitis, pubic symphisitis and right hip joint arthritis in ankylosing spondylitis; (B) Bilateral hip joint arthritis with ankylosis of right hip joint.

Nonsteroidal anti-inflammatory drugs (NSAIDs) form the basis of treatment of this disease. It had to be emphasised that continued usage is beneficial both in maintaining functional capability to carry on with daily activities and also has disease modifying potential. Full dose indomethacin 150 mg per day in an adult will alleviate the symptoms to great extent. In those with gastrointestinal toxicity a selective COX-2 inhibitor could be used with variable efficacy. Analgesics such as paracetamol and opiates may be added for pain control. Corticosteroid injections directed to local site of musculoskeletal inflammation (enthesitis) are useful. The use of systemic corticosteroids for axial disease is not supported by evidence and should be discouraged. Sulphasalazine (SSZ) and methotrexate (MTX) have been used as DMARDs. These drugs are useful in peripheral arthritis but have little or no effect on spinal disease.

Biological agents like anti-TNF-α treatment (infliximab chimeric human/mouse anti-TNF-α monoclonal antibody), etanercept (soluble p75 TNF-α receptor-IgG fusion protein), or adalimumab (human anti-TNF-α monoclonal antibody) are currently indicated with persistent activity despite adequate NSAIDs therapy for 3 months and in case of AS with peripheral arthritis, and patients refractory to adequate trial of SSZ. Infliximab is administered at a dose of 5 mg/kg of body weight intravenously as an infusion diluted with saline over 4 hours. The recommended schedule is 0, 2 and 6 weeks followed by maintenance every 8 weekly to be given for indefinite period. Etanercept is administered at a dose of 25 mg subcutaneously

Figure 2: Radiograph of lumbar spine (lateral view) showing bridging syndesmophytes (white arrowheads) in ankylosing spondylitis joining two adjacent vertebrae.

twice a week. Both of these have been found to be equally effective in improving inflammation and functional quality of life. TNF-α inhibitors reduce the frequency of attacks of uveitis in patients with AS. However, these agents are very expensive and they may lead to reactivation of tuberculosis (TB). The risk of TB is higher with infliximab than with etanercept. It is recommended that a thorough check for TB with Mantoux test and chest radiograph should be done prior to initiation of therapy. The contraindications for starting anti-TNF-α therapy include pregnancy, lactation, previous history of TB, septic arthritis within past 12 months, persistent or recurrent chest infections.

Total hip arthroplasty should be considered in patients with refractory pain or disability and radiologic evidence of damage, independent of age. Spinal surgery, e.g. corrective osteotomy and stabilisation procedure may be of use in selected patients.

REACTIVE ARTHRITIS

Reactive arthritis (ReA) is defined as a sterile joint inflammation within a month following a gastrointestinal or genitourinary infection. Reiter's syndrome which consists of triad of urethritis, arthritis and conjunctivitis is a full blown case of ReA. The full blown cases are a rarity and in many cases the antecedent history of infection is missing yet the clinical picture resembles that of ReA when a label of undifferentiated spondyloarthropathy (uSpA) is used. Rheumatic fever and Lyme disease are forms of reactive and infection-related arthritis that are not associated with HLA-B27 and show a spectrum of clinical features different from spondyloarthritis.

Epidemiology

There are no data available on the incidence and prevalence of ReA from our country. Western data show that incidence is 30 to 40 per 100,000 population.

Pathogenesis

ReA and USpA are triggered by genitourinary infection with *Chlamydia* or gastrointestinal infections with *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter jejuni*, etc. However, the organisms are not isolated from the synovial compartment. The precise mechanisms by which the microbial agent trigger an immune mediated synovitis are not known. Finding of bacterial antigenic fragments and deoxyribonucleic acid (DNA) in some cases suggest that antigen persistence is a plausible mechanism.

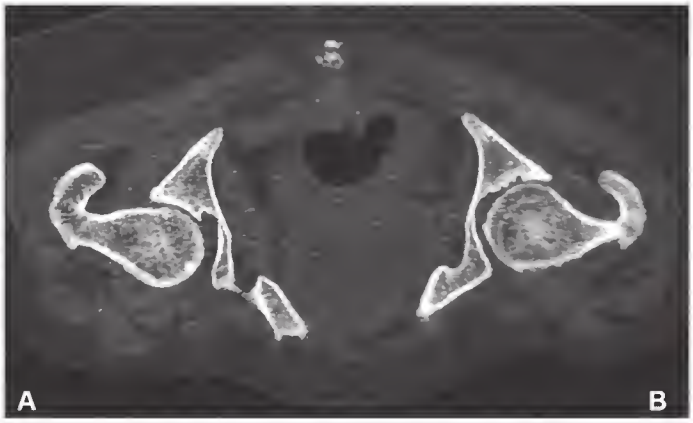

Figure 3: Radiograph of lumbar spine (post-anterior view) showing 'bamboo spine' in ankylosing spondylitis.

Clinical Features

The clinical manifestations of ReA constitute a wide spectrum that ranges from an isolated, transient monoarthritis to severe multisystem disease.

Articular features

ReA presents as an acute onset of mono/oligoarthritis associated with prominent inflammatory features. It may simulate a septic arthritis. A clear-cut history of preceding gastrointestinal or urogenital infection is found in only half of

Figures 4A and B: Computed tomography of hip joint showing bilateral hip arthritis in ankylosing spondylitis.

the patients. The usual age of onset is 20 to 40 years and both sexes are equally affected. Some patients may present with prominent systemic features like fever, fatigue and lack of appetite. In majority of the cases ReA subsides within 12 weeks, but in 30% of cases, it can lead to a chronic or recurrent arthritis. Knee, ankle, subtalar, metatarsophalangeal, and toe interphalangeal joints are involved most commonly; however, upper limb joints may also be involved. Tense joint effusions are not uncommon, especially in the knee. Chronic heel pain may be very distressing. Unilateral sacroiliitis, spondylitis and persistent hip joint disease denotes bad prognosis. HLA-B27-positive patients have shown a worse outcome. Other features include enthesitis, tenosynovitis and dactylitis (sausage digit) which is complete swelling of a digit in the hand or foot.

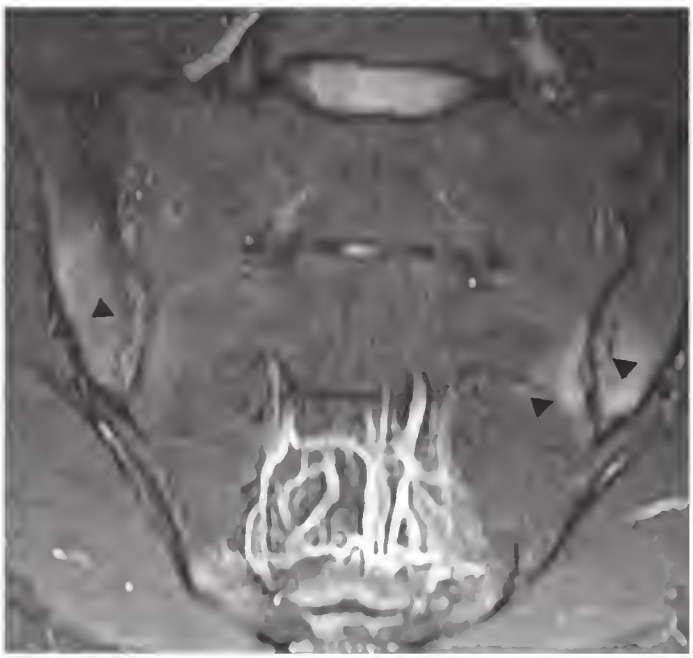

Figure 5: Magnetic resonance imaging of the lumbar spine showing bilateral sacroiliitis with underlying marrow oedema (black arrowheads).

Extra-articular features

Sterile conjunctivitis is the most common lesions; however, anterior uveitis, scleritis, keratitis or even corneal ulcer etc., may also be seen. Non-specific enteritis may be found and patient may present with abdominal pain and diarrhoea. Sterile pyuria and urethritis is quite common (present in about 50% of patients). Increased incidence of IgA nephropathy has been found.

The characteristic skin lesion is keratoderma blenorrhagicum (**Figure 6**) involving the palms and soles and it resembles psoriasis both clinically and histologically. Circinate balanitis is the lesion on the glans penis which consists of vesicles that quickly rupture to form painless superficial erosions. Nail changes are common and consist of onycholysis, distal yellowish discolouration, and/or heaped-up hyperkeratosis. Oral ulcers are usually superficial, transient and often asymptomatic.

Figure 6: Keratoderma blenorrhagicum in reactive arthritis.

Diagnosis

The diagnosis of ReA is based on the typical clinical features. Septic or crystal induced synovitis should be excluded by synovial fluid examination. Synovial fluid examination shows neutrophil leucocytosis. ESR and CRP are usually very high. Demonstration of specific antibodies to *Chlamydia*, *Yersinia* and *Salmonella* in serum by enzyme linked immunosorbent assay is of diagnostic significance in regions where the infection load in the community is less. However, in India, it is of little significance. It is advisable to test for human immunodeficiency virus in patients presenting with ReA. HLA-B27 is present in about 50% of patients with ReA. Plain radiography may show unilateral sacroiliitis and large bulky asymmetrical syndesmophytes.

Natural History

Prognosis is generally good. A typical episode lasts for about 3 to 5 months. About one-third of the patients suffer a single episode only, another one-third recurrent episodes and rest one-third chronic ReA. The presence of HLA-B27 favours development of chronic ReA.

Differential Diagnosis

The common differential diagnoses are septic arthritis (especially, gonococcal arthritis) and crystal arthropathy. Gonococcal arthritis typically presents with migratory arthritis involving both upper and lower limbs, prominent tenosynovitis, vesicular skin lesions and absence of inflammatory low backache. A positive gonococcal culture from skin lesions or urethral/cervical discharge is confirmatory.

Management

Rest to the affected joints and immobilisation till the acute inflammation subsides is advocated. Within first few weeks of the disease, the joint should not be used vigorously as even minor trauma may lead to recurrence. Indomethacin or other NSAIDs may be tried. Indomethacin is given as 75 to 150 mg

per day in divided doses till the arthritis resolves. Intra-articular injection of corticosteroids may be given when rapid control of inflammation is required. Local injection of corticosteroids may be given for tenosynovitis or enthesitis. However, there is no evidence to support that treatment with corticosteroids will prevent subsequent relapse.

Sulphasalazine, 2 to 3 g per day in divided doses, may be beneficial in patients having persistent ReA for more than 6 months. Patients with persistent disease may also respond to azathioprine (1 to 2 mg/kg per day), or to methotrexate (10 to 20 mg per week). In severe chronic cases anti-TNF-α may be useful.

Uveitis is usually treated with local administration of corticosteroid drops or injections and mydriatics.

PSORIATIC ARTHRITIS

It is defined as arthritis associated with psoriasis and usually negative for RF. The classification criteria for psoriatic arthritis (PsA) are shown in **Table 7** with a sensitivity of 91% and specificity of 98%.

Table 7: Classification Criteria for Diagnosis of Psoriatic Arthritis

A patient must have inflammatory articular disease (joint, spine or enthuses) with 3 or more points from the following five categories:
Evidence of current psoriasis, a personal, or a family history of psoriasis
Typical psoriatic nail dystrophy
A negative test result for the presence of rheumatoid factor by any method except latex
Either current dactylitis or history of dactylitis recorded by a rheumatologist
Radiographic evidence of new bone formation appearing as ill-defined ossification near joint margins

Epidemiology

Psoriasis affects ~1% of the population and arthritis affects 5% to 10% of patients with psoriasis.

Pathogenesis

PsA as well as psoriasis is a T-cell-mediated disease. There is upregulation of leucocyte-homing receptors in synovium which results in leucocyte infiltration of synovium. Cytokines are secreted by leucocytes which mediate arthritis.

Clinical Features

The mean age of onset of arthritis is 30 to 55 years. About two-thirds of the patients develop arthritis after onset of skin psoriasis, in 15% both arthritis and psoriasis occur within 12 months of each other and in the remaining arthritis precedes onset of skin lesions by more than 12 months.

Skeletal manifestations

There are five distinct patterns of joint involvement in psoriatic arthropathy. These include: distal interphalangeal (DIP) joint arthritis (15%); oligoarticular arthritis (30%); symmetrical rheumatic arthritis (RA) like arthritis (40%); spondylitis (20%); and arthritis mutilans (5%). A simpler scheme in recent use contains three patterns: oligoarthritis, polyarthritis, and axial arthritis. RA like symmetrical arthritis subset is negative for RF. There are some joints which are typically involved in PsA which include temporomandibular, manubriosternal and DIP joints (**Figures 7 and 8**). Isolated spondylitis without peripheral arthritis is very rare and found in 1% to 5% of patients with PsA. The spondylitic variety can mimic AS except that sacroiliac joints may be unilaterally involved and syndesmophytes are non-symmetrical. The DIP joint arthritis is usually associated with nail involvement. Apart from arthritis, enthesitis and dactylitis occur in one-third of patients. Poor prognostic factors are polyarticular disease (≥4 joints), presence of joint damage (erosions) and impairment of functional status. Shortening of digits because of underlying osteolysis is particularly a characteristic of PsA.

Figure 7: Hand in psoriatic arthritis showing skin psoriasis lesions, distal interphalangeal joint arthritis and nail changes.

Figure 8: Radiograph of hands showing distal interphalangeal joint involvement in psoriatic arthritis.

Skin manifestations

The evidence of typical plaque having silvery scales has to be looked for carefully particularly in hidden sites such as underneath the breast, navel, scalp, behind the ears, and extensor aspects of knees, elbows and back. The nails have to be observed for pits and onycholysis (**Figure 8**). Nail involvement is found more commonly in PsA (90%) compared to psoriasis without arthritis (40%). Patterns of nail involvement

include pitting, horizontal ridging, onycholysis, yellowish discolouration of the nail margins, dystrophic hyperkeratosis, and combinations of these findings.

Investigations

Inflammatory parameters (ESR and CRP) may be elevated. RF and antinuclear antibody are usually negative. Hyperuricaemia is seen in up to 20% of patients and is related to renal insufficiency and not to epidermal turnover as was previously thought. HLA-B27 is found in 50% to 70% of patients with axial disease, but 15% to 20% in patients with only peripheral joint involvement.

Radiologically, the distinguishing features as opposed to RA are less of juxta-articular osteopoenia, presence of periostitis, ankylosis, asymmetric involvement of peripheral joints, sacroiliitis and asymmetric bulky syndesmophytes. Pencil-in-cup deformity is characteristic of psoriasis. Erosions are seen in 35% to 50% of patients.

Management

Therapy should be directed at both the skin and joints in PsA. NSAIDs are the initial therapy for patients presenting with pain, swelling and stiffness. These are not beneficial in skin disease. DMARDs like MTX, SSZ, cyclosporine and azathioprine have variable effects on arthritis. Anti-TNF-α therapy (etanercept, infliximab) substantially improves peripheral arthritis, functional status, skin lesions and quality of life. The pyrimidine synthetase inhibitor leflunomide has been shown to be beneficial in both psoriasis and psoriatic arthritis. Other agents with efficacy in psoriasis reported to benefit PsA are retinoic acid derivatives, and psoralen plus ultraviolet light.

INFLAMMATORY BOWEL DISEASE-ASSOCIATED ARTHRITIS

Inflammatory bowel disease (IBD)-associated arthritis is defined as arthritis associated with ulcerative colitis (UC) and Crohn's disease (CD). Arthritis is the most common extra-intestinal manifestation and seen in 2% to 20% of patients with IBD. Radiographic sacroiliitis is more common. No data on incidence of arthritis in IBD is available from our country.

Clinical Features

Young and middle-aged adults are commonly affected and both sexes are equally represented.

Peripheral arthritis

Peripheral arthritis is subdivided into two groups; type 1 and type 2 arthritis. Type 1 arthritis involves less than 5 joints and are acute, self-limiting attacks often coinciding with relapse of IBD. Type 2 on the other hand are polyarticular involving 5 or more joints and are chronic which run a course independent of IBD and is associated with uveitis. Type 1 is seen in 3.6% of patients with UC and 6% patients with CD. Type 2 arthritis is found in 2.5% of patients who suffer from UC and 4% of patients with CD.

Sacroiliitis and spondylitis

Sacroiliitis and spondylitis is more common in males (ratio 3:1) and resembles AS both clinically and radiologically. These may precede bowel disease by many years. Enthesitis and dactylitis are seen as in other members of SSA.

Extra-articular features

Acute anterior uveitis is the most common ocular manifestation. It is associated with HLA-B27 and axial joint involvement. Skin rash is seen in 10% to 25% of patients and erythema nodosum is the most common skin rash and is associated with relapse of IBD. Pyoderma gangrenosum and secondary amyloidosis is infrequent.

Investigations

Common laboratory findings are iron deficiency anaemia, leucocytosis and thrombocytosis. The inflammatory parameters (like ESR, CRP) are usually elevated. Radiologically, the axial involvement of AS and IBD-associated arthritis are similar. Peripheral arthritis with erosions is seen.

Management

The treatment of IBD should be the primary aim. Managing IBD will take care of most of the peripheral arthritis. For patients presenting with pain and disability, NSAIDs are the first choice. However, they may aggravate UC. SSZ is effective in both types of IBD and MTX is useful in CD but its efficacy in associated arthritis is not known. Infliximab is now being used in treatment-resistant CD and treatment-refractory CD-associated arthritis.

JUVENILE ANKYLOSING SPONDYLITIS

Juvenile ankylosing spondylitis is a type of juvenile idiopathic arthritis (JIA). Presently it is known as JIA-ERA (enthesitis-related arthritis). It is called juvenile when the onset is before 16 years of age. The diagnostic criteria of JIA-ERA are given in **Table 8**.

Table 8: Diagnostic Criteria for JIA-ERA

Arthritis and enthesitis, or arthritis or enthesitis with at least two of the following features:
Presence of or a history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain
Presence of HLA-B27 antigen
Onset of arthritis in a male over 6 years of age
Acute (symptomatic) anterior uveitis
History of AS, ERA, sacroiliitis with IBD, Reiter's syndrome or acute anterior uveitis in a first-degree relative
Psoriasis, RF and systemic-onset JIA should be excluded

Management

These are treated on the same lines as adult disease.

UNDIFFERENTIATED SPONDYLOARTHRITIS

Patients presenting with one or more features of spondyloarthritides but not fulfilling the criteria are known as undifferentiated spondyloarthritis (USpA), e.g. patients presenting with clinical feature suggestive of ReA but does not have any evidence of antecedent gastrointestinal or genitourinary tract infection are to be labelled as USpA. About 50% of such patients are HLA-B27 positive and thus HLA-B27 positivity is not useful in making or excluding a diagnosis. Over time, some of such patients may evolve into definitive arthritis.

24.8 Sjögren's Syndrome

Uma Kumar

Sjögren's syndrome (SS) is a chronic autoimmune exocrinopathy characterised by lymphocytic infiltration of lacrimal and salivary glands. It is a systemic disease named after the Swedish ophthalmologist, Henrik Sjögren, who introduced the term 'keratoconjunctivitis sicca' for dryness of eyes noted in patients. The SS may exist as primary SS (pSS) or secondary SS (sSS) occurring in association with other systemic autoimmune diseases, like rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus, polymyositis, etc. The prevalence of pSS is 0.1% to 0.6% according to the American European Consensus criteria with female to male ratio of 9:1. It has two age peaks, with first in the twenties and the second in the fifties.

AETIOPATHOGENESIS

The pSS is a multisystem autoimmune disease with complex interaction between innate and adaptive immunity and salivary glands dysfunction. Environmental factors (viral/other intercurrent infections) are thought to trigger inflammation in a genetically predisposed individual. There is infiltration of glandular tissue by CD4+ T-lymphocytes. The glandular epithelial cells express high levels of HLA-DR which presents viral antigens or autoantigens to the CD4+ T-lymphocytes. This sets in process an inflammatory cascade with cytokine production, notably interferon-gamma (IFNγ) and (interleukin (IL)-2. CD20+ B-cell constitutes a significant component of periductal foci and patients demonstrate evidence of B-cell activation with resultant autoantibody production. In addition to the presence of antibodies to SS-A/anti-Ro and SS-B/anti-La, two-thirds of the patients also have serum antinuclear antibody (ANA) and rheumatoid factor (RF), particularly IgA-containing RF. Polyclonal hypergammaglobulinaemia is common.

CLINICAL MANIFESTATIONS

The SS has diverse clinical manifestations ranging from limited exocrinopathy to widespread autoimmune non-exocrine systemic manifestations. Non-exocrine involvement is of two types: (1) Periepithelial infiltrative processes which generally follow a benign course. It includes interstitial nephritis, liver involvement, and bronchiolitis; and (2) Extraepithelial processes which result from B-cell hyper-reactivity, hypergammaglobulinaemia, and immune complex formation. It includes palpable purpura, glomerulonephritis, and peripheral neuropathy. Systemic manifestations of pSS are given in **Table 1**.

Ocular

Patients are usually unaware of dry eyes but may complain of gritty sensation, photophobia, redness, thick mucus strands and encrusted eyelids on awakening in the morning. If untreated, the condition may result in corneal abrasion, ulcer, or infection.

Oral

Patients usually complain of difficulty in eating without the help of liquids and parched feeling in the mouth and throat. Dental caries and oral candidiasis occur frequently owing to decreased salivary flow. It is important to realise that in pSS the mouth is dry but not painful. In case of painful mouth, one must suspect fungal infection. Patients are prone to develop ductal calculi because of thick inspissated saliva in parotid ducts. A hard mass in parotid should raise suspicion of malignancy. Recurrent bilateral parotitis occurs in majority of the patients but sublingual and submandibular glands can also be affected. Approximately 40% patients also develop dryness of skin, nose and vagina.

Table 1: Systemic Features of pSS

Musculoskeletal (60%): Arthralgia, myalgia, non-erosive arthritis
Pulmonary (75%): Xerotrachea (manifest as a dry cough), interstitial lung disease, recurrent bronchitis, bronchial hyper-responsiveness, pneumonitis
Gastrointestinal: Dryness of the pharynx and oesophagus, gastroesophageal reflux, rarely pancreatitis
Cardiac: pericarditis, pulmonary hypertension
Nervous system (8% to 40%): Myelopathy, optic neuropathy, seizures, cognitive dysfunction, and encephalopathy, cranial neuropathies, mononeuritis multiplex, sensory, motor, or sensorimotor peripheral neuropathy, distal paraesthaesia
Renal: Interstitial nephritis, renal tubular acidosis, interstitial cystitis, rarely glomerulonephritis

Vascular

Vasculitis has been found in approximately 15% of pSS patients. Majority of patients present with cutaneous vasculitis ranging from hypersensitivity vasculitis to necrotising vasculitis. Palpable purpura worsening on prolonged standing is the usual presentation. One must exclude hepatitis C virus (HCV) infection if patient presents with cutaneous vasculitis, cryoglobulinemia and sicca symptoms. Raynaud's phenomenon is reported in 15% patients, rarely results in digital ulcers.

DIAGNOSIS

It is not difficult to diagnose SS in the presence of keratoconjunctivitis sicca, dryness of mouth and characteristic autoantibody profile (presence of ANA, anti SS-A and anti SS-B antibodies). However, problem arises if patient has mild symptoms and less characteristic antibody profile; anti Ro/SSA and anti-La/SSB occur in approximately 60% of the patients with pSS.

Previously, minor salivary gland biopsy was thought to be gold standard but it was realised that lymphocytic infiltrate can be modified by various factors. Only samples demonstrating foci of mononuclear cells (cluster of atleast 50 lymphocytes) should be reported as compatible with pSS. International Sjögren's syndrome research community has established classification criteria which permits diagnosis without minor salivary gland biopsy and also gives clear cut exclusion criteria. It is important to exclude secondary causes of sicca symptoms as no test is pathognomonic of pSS.

Schirmer's test, Rose-Bengal test and tear break time are all sensitive but only Rose-Bengal test is specific (>95%). Sialography seems to be as sensitive as lip biopsy but less specific. Recently, MRI has been found to be relatively more sensitive and specific for glandular involvement in pSS.

Differential Diagnosis

1. Diffuse infiltrative lymphocytosis syndrome: It commonly occurs in males with human immunodeficiency virus infection. Although 10% of these patients may have ANA and RF positive but SS-A and SS-B antibodies are absent. Immunohistochemistry of minor salivary gland helps in difficult cases.
2. Sarcoidosis: Characteristic features of sarcoidosis along with histology suggestive of non-cascating granulomas.
3. Lymphoma: It usually presents with firm painless masses in parotid gland.
4. Graft versus host disease: Significant proportions of patients have ANA and RF positivity but not SS-A and SS-B positivity. Minor salivary glands CD4+/CD8+ ratio is either low or inverse in comparison to pSS where it is more than 3.0.

Sicca symptoms can occur with ageing, amyloidosis, fibromyalgia, and certain drugs.

MANAGEMENT

Management of pSS requires collaborative effort from ophthalmologist, dental surgeon, pulmonologist, and rheumatologists.

Treatment of Dry Eyes

Adequate ophthalmic care is required to prevent corneal ulceration and its sequelae.

Preservation of tear film

Preservation of tear film can be achieved through: (1) avoiding humid environment and eye irritants, like smoke or dust; (2) avoiding activities that provoke tear film instability, e.g. prolonged hours on computers, prolonged reading hours etc.); (3) avoiding medicines causing ocular dryness (anticholinergic agents, antihistamines, diuretics, beta blockers etc.); and (4) punctual occlusion (punctal plugs, permanent occlusion by surgery or cautery) in moderate to severe cases. Goggles with specially constructed side chambers also help in reducing tear evaporation. It is better to avoid contact lenses as they may worsen dryness and predispose eye for infection.

Tear replacement

Artificial tear preferably preservative free during daytime and lubricating ointment during night is advisable. Tear substitutes must be refrigerated and discarded after single use.

Stimulation of residual lacrimation

Muscarinic receptor agonists stimulate existing lacrimal cells to increase tear production. Pilocarpine 5 mg three to four times per day or cevimeline 30 mg three times daily (currently not available in India) brings subjective and objective improvement in patients. Nausea, sweating, headache, and abdominal pain are possible side effects. Caution is required in narrow angle glaucoma, asthma, acute iritis, cardiovascular diseases and Parkinsonism. Maximal therapeutic effect may require 12 weeks of therapy in some patients. Cyclosporin A 0.05% ophthalmic emulsion in moderate to severe dry eye has shown significant improvement without any significant adverse effect. Common adverse effects have been eye irritation and conjunctival hyperaemia but soon tolerance develops. Cyclosporin decreases the conjunctival lymphocytosis and increases conjunctival goblet cells along with having antiapoptotic properties. Topical corticosteroids are of limited value in the management of dry eyes. Other drugs being tried out include rebamipide, tacrolimus and diquafosol tetrasodium.

Treatment of Dry Mouth

It includes adequate hydration and avoidance of tea, coffee and nicotine, drugs causing dryness of oral mucosa. Frequent sips of water may also help. Good oral hygiene and dental care must be emphasised. Use of fluoride (fluoride gel, toothpaste, or rinses containing 0.4% to 1.25% fluoride) is helpful. Sugar free chewing gum and lozenges may stimulate salivary flow. Oral candidiasis must be promptly treated with antifungals. Saliva substitutes (gels, mouthwashes, lozenges) may be used to improve lubrication and hydration of oral mucosa but their effect is short lasting. The muscarinic agonist, pilocarpine and cevimeline, improve salivary flow depending on residual secretory capacity of salivary glands.

Systemic Treatment

Nonsteroidal anti-inflammatory drugs (NSAIDs) and analgesics are the first line treatment for musculoskeletal symptoms. Hydroxychloroquine sulphate (6-7 mg/kg/day) may be used in patients having arthralgia, myalgia and fatigue. Short course of low dose corticosteroids (prednisolone 10-20 mg/day) may be given for painful debilitating joint disease. Diseases modifying anti-rheumatic drugs are usually not required for arthritis. Pilocarpine and cevimeline has been found to be of some relief in patients with skin dryness. Steroid creams may help in relieving pruritus. Mild cases of leucocytoclastic vasculitis may be treated expectantly, whereas severe cases require more aggressive immunosuppressive therapy. Persistent dry cough because of xerotrachea may respond to humidification, secretagogues and guaifenesin (1200 mg twice a day). Major organ vasculitis, interstitial lung involvement and central nervous system involvement may require high dose corticosteroids along with cyclophosphamide. Rituximab, a chimeric monoclonal antibody to CD20, leads to B-cell depletion and is emerging as a promising treatment for systemic complications of pSS.

Special Situations

1. During surgery, special precautions must be taken to avoid undue drying of eyes and mouth. Anaesthetist must be careful with the amount of anticholinergic given during intubation.
2. Presence of anti-Ro/SS-A in pSS may predispose the foetus to congenital heart block, and neonatal lupus. Close foetal monitoring is a must.
3. The pSS has approximately 40-fold increased risk of developing non-Hodgkin's lymphoma compared to age-matched controls.

24.9 Systemic Lupus Erythematosus

VR Joshi

DEFINITION AND EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is a chronic immuno-inflammatory disease of unknown aetiology, that involves several organ systems and body tissues. Multiple autoantibodies are present. The disease course is variable with periods of inactivity, or low-grade activity punctuated with periods of increased disease activity (flares). The disease carries significant morbidity and mortality.

The annual incidence of SLE in the United States and Europe has been estimated to be 2 to 8 per 100,000 population and estimates of its prevalence range between 20 to 60 cases per 100,000 population. There is paucity of Indian data. In a study conducted near Delhi, the prevalence of SLE was found to be 3.2 per 100,000 population, one of the lowest in the world. More recent studies corroborate the same. The incidence of SLE is higher in American blacks, Afro-Carribeans and Indian immigrants in UK. The incidence of SLE has probably increased over the last few decades. Part of the increase may be due to increased awareness and the ready availability of diagnostic tests (apparent increase).

More than 85% of SLE patients are females. The male to female ratio tends to be equal in the very young and the old. The majority of patients are between 20 and 50 years of age.

AETIOLOGY

The exact aetiology is not known. Genetic, hormonal, and environmental factors play a role (**Table 1**). SLE is a polygenic disorder. Multiple genetic susceptibility loci have been identified. Their relative contributions and interactions are not clearly understood. Genetic factors alone do not explain the disease susceptibility. Concordance of SLE in monozygotic twins is 25% (2% in dizygotic twins). A variety of environmental factors have been incriminated. Hormonal (and possibly genetic) influence is reflected in the female preponderance. Infections most likely play a facilitatory role though no specific infective organism has been incriminated. Breastfeeding, progesterone, 1, 25(OH)D_3, omega-3 fatty acids are said to reduce SLE risk.

PATHOGENESIS

SLE is characterised by hyper-reactivity of B lymphocytes hypergammaglobulinaemia, multiple organ-specific and non-organ-specific autoantibodies, circulating immune complexes, and complement activation (low C_3, C_4, increased C_3, C_4 activation products). Antinuclear antibodies (ANA), the hallmark of SLE, can precede clinical manifestations by many years. Only 2% of ANA positive asymptomatic individuals go on to develop SLE. Cellular immunity is aberrant. There is leucopaenia, lymphopenia and monocytosis. Breakdown of tolerance to self antigens, increased apoptosis and impaired clearance of apoptotic bodies are thought to play an important role in pathogenesis. The mechanism of tissue damage is the result of immune complex deposition as well as direct cellular injury.

Table 1: Aetiological Factors in SLE*

Genetic factors
HLA B8, DR 3, DR 2
Inherited complement deficiencies (C4a-null alleles, C1q, C1r/s)
FcRλ gene polymorphism (weak binding with IgG)
Others: Ig receptors, kinases, signalling molecules, cytokines
Non-genetic factors
UV light (inflammation and tissue damage)
Physical and emotional stress (neuroendocrine changes affecting immune cell function)
Infection—EBV, CMV (molecular mimicry, disturbed immuno-regulation)
Female sex-hormones (oestrogen); (prolactin—pregnancy flare)
Diet—(production of inflammatory mediators)
Drugs—Procainamide, quinidine, hydralazine, methyldopa, chlorpromazine, isoniazid, biologicals, etc. (modify self antigens, methylation changes in promoter genes and cellular response)
Environmental factors—smoking, silica

** List not exhaustive. Not all have sufficient evidence. Genetic factors are likely to vary amongst different ethnic groups.*

Autoantibodies (Table 2)

Autoantibodies are directed against various cellular components (nuclear, cytoplasmic, cell membrane), and soluble molecules such as IgG and coagulation factors. Amongst these ANAs are most characteristic. Antibodies to dsDNA, and Sm are exclusive to SLE. Anti-dsDNA, anti-Sm, and anti-Ro antibodies are incriminated in the pathogenesis of lupus nephritis. Other associations are anti-P with neuropsychiatric lupus and hepatitis, anti-Ro with neonatal lupus, antiphospholipid with thrombosis, thrombocytopaenia and recurrent abortions and antibodies to blood cells with cytopaenias.

CLINICAL MANIFESTATIONS

The clinical features and presentations of SLE are extremely variable. SLE may present acutely with non-specific constitutional symptoms such as fever, arthralgias, rash, weight loss, lymphadenopathy or as a single organ disease, e.g. nephritis. The disease may evolve over time (sometimes over years) delaying the diagnosis, e.g. arthritis may be the only manifestation for years. The severity of the disease is variable, ranging from a benign mild disease to a severe life- or organ-threatening disorder. Arthritis, arthralgias, fever, and rash are the most common presenting manifestations. Fatigue is a prominent constitutional symptom. Other constitutional symptoms are malaise, weight loss and headache. The cumulative frequency of clinical manifestations is depicted in **Table 3**.

Table 2: Common Autoantibodies in SLE

Autoantibody	Frequency (%)	Specificity	Clinical Association
ANA	98 to 100	Not specific	Not exclusive to SLE
Anti-dsDNA	40 to 70	Most specific	Nephritis
Anti-Sm	5 to 40	Highly specific*	? Nephritis,? neuropsychiatric lupus CNS
Anti-Ribosomal P	10 to 15	Highly specific	Psychosis
Anti-Histone	40 to 80	Not specific	Drug-induced lupus
Anti-Ro (SS-A)*	15 to 40	Not specific	Subacute cutaneous lupus, photosensitivity, neonatal lupus, congenital heart-block, ANA –ve lupus, secondary Sjögren's syndrome
Anti-La (SS-B)	10 to 15	Not specific	Rarely present without anti-Ro antibodies
Anti-U-1 RNP	30 to 40	Not specific	Raynaud's phenomenon, oesophageal dysmotility, myositis (MCTD)
Anti-cardiolipin	20 to 25	Not specific	Thrombosis, foetal loss, thrombocytopaenia, secondary antiphospholipid syndrome
Anti-ssDNA	90	Not specific	—

** Higher frequency in Blacks and Indians.*

Table 3: Cumulative Frequency of Clinical Features of SLE

Feature	Indian Data (%)	Western Data (%)
Arthritis	72 to 92	86 to 94
Alopaecia	52 to 80	50
Skin rash	74 to 90	60
Photosensitivity	10 to 62	33 to 62
Malar rash	37 to 76	72 to 90
Oral ulcers	41 to 61	30
Fever	74 to 91	80
Lymphadenopathy	26 to 47	50
Neuropsychiatric	19 to 63	20 to 45
Renal	35 to 73	29 to 73
Cardiac	10 to 29	20 to 30
Pleuropulmonary	9 to 54	36 to 57

Mucocutaneous

Skin

Acute, subacute or chronic cutaneous manifestations are present in 80 to 90% of patients. Apart from the classical malar rash (seen in less than 50% of patients), rash is characteristically present in the pre-auricular, auricular, and post-auricular areas. There may be diffuse hyperpigmentation or diffuse maculopapular rash. Discoid lesions, seen in 15 to 30% of SLE patients, are not restricted to face and scalp. Livedo reticularis is typical of associated antiphospholipid syndrome (APS). Subacute cutaneous lupus (SCLE) (present in up to 25% patients) is characterised by the presence of photosensitive, superficial, non-indurated, non-scarring annular or papulosquamous psoriasis-like lesions. Anti-Ro antibodies are commonly associated with SCLE. Other cutaneous manifestations include bullous lesions, splinter haemorrhages, subcutaneous nodules, leg ulcers, and lupus profundus. Rash is often precipitated or aggravated by exposure to sunlight.

Mucous membranes and scalp

Mucous membranes of oral cavity, nose, and vagina are involved. Oral ulcers are usually small, multiple, and painless (**Figure1**). Palatal erythema at the junction of hard and soft palate indicates active disease. Though mostly painless, it may sometimes evolve into painful ulceration. Non-scarring diffuse alopaecia is common (**Figure 2**). With disease control, the hair regrow. Scarring alopecia due to discoid lesions is permanent. Scalp tenderness is sometimes present and indicates active disease.

Figure 1: Oral ulcers in SLE.

Vasculocutaneous lesions

Vasculocutaneous lesions are important markers of disease activity. The spectrum includes Raynaud's phenomenon (rarely digital gangrene), urticaria, palpable purpura, nail fold lesions, and splinter haemorrhages. Palmar vasculitic lesions resemble Osler's nodes and Janeway's lesions. Elbow is a common site of cutaneous vasculitis.

Figure 2: Alopaecia in SLE.

Musculoskeletal

Arthritis or more commonly arthralgias are one of the most frequent presenting manifestation of lupus with a cumulative frequency of >90%. Small joints of both the hands, wrists, and knees are mostly affected. Synovitis is usually less marked and the pain may seem to be out of proportion. Deformities of fingers are uncommon; when present these are typically reducible (Jacoud's arthropathy; it is due to tenosynovitis). Erosive arthritis is rare. Avascular necrosis (AVN) and infection should be suspected when a SLE patient presents with sudden onset, persistent pain and/or swelling of one or few joints. Hip, often bilateral, is the most common site of AVN. Tenosynovitis and tendon rupture can occur. Inflammatory myositis with muscle weakness is seen in a few patients. Myalgia is more frequent. CPK may not be raised. Steroid and chloroquine induced myopathy is an important exclusion. Fibromyalgia is common.

Renal

Renal involvement, present in more than 50% of patients, is an important determinant of prognosis. Clinically it may manifest as nephritis or nephrotic syndrome but can be asymptomatic (**Table 4**). Renal thrombotic angiopathy due to APS and tubulointerstitial disease are other manifestations. Unexplained hypertension should suggest renal involvement. Regular (monthly, initially) urine examination and serum creatinine estimation ensure early diagnosis. Proteinuria (dip stick 2 + or > 500 mg/24 hrs) with or without RBC casts is the most common laboratory indicator of renal involvement. Isolated haematuria (>5 RBC/HPF) or leucocyturia (>5 WBC/HPF) are uncommon presentations and need exclusion of other causes. Renal disease is usually preceded by high anti-dsDNA antibody titres and low C_3, C_4 levels. The biochemical correlates of lupus nephritis (LN) are elevated serum creatinine and low albumin. LN in Indians tends to be severe. Renal biopsy, though not essential for the diagnosis, is useful to assess severity, nature, and reversibility or otherwise of renal involvement. WHO classification of LN is being replaced by histologic classification of lupus nephritis as per the International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 (**Table 5**). Diffuse proliferative glomerulonephritis (class IV) is the most common histologic type). Untreated nephritis results in chronic renal failure.

Neurological

Neuropsychiatric lupus (NSL) is the second serious manifestation of SLE, being associated with significant morbidity and mortality. Its pathogenesis is not clear. Vasculopathy, thrombosis and antibody induced cell damage or dysfunction are thought to play a role. Manifestations are diverse. Headache including migraine and subtle cognitive dysfunction are common. Other psychiatric manifestations include anxiety, acute confusional state and psychosis. Convulsions, focal motor and sensory deficits (stroke, movement disorders, cranial neuropathies, paraplegia), cerebritis, peripheral neuropathies and autonomic dysfunction are other manifestations. Myelopathy, meningitis, and chorea are rare. Primary neuropsychiatric diseases, infection, steroid psychosis, and metabolic disorders are important differential diagnoses. CSF examination, CT, MRI and PET scan are of variable diagnostic value.

Cardiovascular

Pericarditis, the most common cardiac manifestation, is often silent. Large pericardial effusion, cardiac tamponade, and constrictive pericarditis are rare. Myocarditis may present as unexplained tachycardia, heart failure, arrhythmia or heart-block. Mitral and aortic valve involvement can be clinically significant. With the availability of echocardiogram, Libman-Sacks endocarditis, the classical cardiac manifestation of SLE, is diagnosed more frequently. It is often associated with anti-phospholipid antibodies. The risk of infective endocarditis is increased. Coronary arteritis is rare. Accelerated atherosclerosis is an important late complication and a major cause of premature death. Traditional risk factors apart, SLE itself and corticosteroid use are independent risk factors for premature atherosclerosis.

Pulmonary

Pleurisy and pleural effusion are the most common pulmonary manifestations. Lupus pneumonitis, alveolar haemorrhage, and pulmonary arterial hypertension, though rare, are life-threatening manifestations. Lupus pneumonitis needs to be differentiated from infective pneumonia. Interstitial lung disease is sometimes encountered. Pulmonary tuberculosis may complicate immunosuppressive therapy. Shrinking lung syndrome is a rare manifestation. Pulmonary embolism is associated with APS.

Haematological

Anaemia of chronic inflammation is common. Concomitant iron deficiency may be present. Coombs' positive anaemia is sometimes the initial manifestation of SLE. Leucopaenia and lymphopaenia are characteristic and correlate with disease activity. Cytopaenias are most commonly due to peripheral destruction and not due to marrow suppression which is often secondary to medications. Thrombocytopaenia may be due to

Table 4: Histologic Class, Clinical Presentation, Prognosis and Treatment of Lupus Nephritis

Histologic Type	WHO Class	Frequency (%)	Proteinuria (%)	Nephrotic Syndrome (%)	Azotaemia (%)	Death (%)	Uraemic Death (%)	Treatment
Normal	I	<5	—	—	—	—	—	—
Mesangial	II	15	68	0	12	18	—	Steroids + rarely IS
Focal proliferative	III	20	100	15	18	30	11	Steroids + IS
Diffuse proliferative	IV	50	100	87	75	58	36	Steroids + IS*
Membranous	V	15	100	88	20	38	6	Steroids + IS

** and others such as plasmapheresis, biologics; IS = Immunosuppressives*

Table 5: Histological Classification of Lupus Nephritis According to the International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 [(ISN/RPS (2003)]

WHO Type (1995)	Description
Class 1	Minimal mesangial lupus nephritis Normal glomeruli by light microscopy but mesangial immune deposits by immunofluorescence
Class 2	Mesangial proliferative Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits A few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy, but not by light microscopy
Class 3	Focal lupus nephritis Active or inactive focal, segmental or global endo- or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class 4	Diffuse lupus nephritis Active or inactive diffuse, segmenal or global endo- or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided to diffuse segmental (IV-S) lupus nephritis, when ≥50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) when ≥50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation
Class 5	Membranous lupus nephritis Global or segmental subepithelial immune deposits or their morphological sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations Class 5 nephritis may occur in combination with class 3 or class 4 in which case both will be diagnosed Class 5 nephritis may show advanced sclerotic lesions
Class 6	Advanced sclerotic lupus nephritis ≥90% of the glomeruli globally sclerosed without residual activity

autoimmune destruction of platelets or because of APS. Idiopathic thrombocytopaenic purpura (ITP) may antedate SLE by years. Lymphadenopathy is common. Thrombotic thrombocytopaenic purpura, bone marrow aplasia and functional hyposplenism are rarely encountered. ESR is elevated. CRP is often undetectable except in the presence of significant inflammation or infection.

Antiphospholipid syndrome (APS)

Twenty to twenty-five per cent patients of SLE test positive for antiphospholipid antibodies. The syndrome of APS is discussed separately.

Others

Abdominal pain may be due to mesenteric vasculitis, aseptic peritonitis or pancreatitis and indicates active disease. Mesenteric vasculitis may manifest with rectal bleeding. Protein-losing enteropathy is uncommon. Though parenchymal liver disease is uncommon, elevated SGOT, SGPT levels are present during active disease and/or with therapy (NSAIDs, azathioprine, methotrexate). Jaundice is uncommon. Hepatomegaly and splenomegaly are present in 25% and 10% of patients. Conjunctivitis, keratoconjunctivitis sicca, episcleritis, and retinitis are some of the ocular manifestations. Uveitis and scleritis are rare.

DIAGNOSIS

The American College of Rheumatology (ACR) has established classification criteria (**Table 6**). Though these are meant for classification and not for diagnosis, most physicians use these to diagnose SLE. A clinically diagnosed or suspected case of SLE may not satisfy the criteria, as these can evolve over time. Treatment decisions should not be delayed, till classification criteria are satisfied. Further many of the common clinical features such as alopecia, constitutional symptoms, vasculitis and rash are not included in the classification criteria. The common differential diagnoses are other autoimmune connective tissue disorders, primary vasculitides and systemic onset JIA.

INVESTIGATIONS

Following biochemical investigations are routinely carried out:

- CBC
- ESR
- Urine routine
- Serum creatinine

These are repeated periodically (monthly or at longer intervals).

Immunology investigations:

- ANA (not required to be repeated)
- Anti-dsDNA
- ENAs (Antibodies to extractable nuclear antigens) viz., Ro (SSA), La (SSB), Smith, RNP, etc.
- C3, C4
- Antiphospholipid antibodies

Others:

- X-ray chest
- Special investigations as indicated

Disease Activity Assessment

Assessment of disease activity is important as therapy depends upon severity of disease activity and the organ system involved. **Table 7** shows investigations indicated as per individual organ involvement. Periodic complete blood counts and urine analysis are mandatory. Active lupus is frequently characterised by anaemia, leucopaenia, lymphopaenia, and thrombocytopaenia (differential diagnosis being drug-induced cytopaenias). Proteinuria and active urinary sediment point to active glomerulonephritis. Rising anti-dsDNA antibody titres and falling C_3, C_4 levels predict/anticipate disease flare. Renal biopsy is useful to assess renal involvement.

Table 6: 1982 revised ACR Criteria for Classification of SLE (Updated 1997)

Criterion	Definition
Facial erythema (butterfly rash)	Fixed erythema, flat or raised over the malar eminences, tending to spare the nasolabial folds
Discoid lupus	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in the older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient's history or physician's observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterised by tenderness, swelling or effusion
Serositis	Pleuritis, convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion or Pericarditis documented by ECG or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria greater than 0.5 gm/day or greater than 3+ if quantitation not performed or Cellular casts, may be red cell, haemoglobin, tubular or mixed
Neurologic disorders	Seizures or psychosis, other causes ruled out
Haematologic disorder	Haemolytic anaemia, leucopaenia (<4000 mm^3), lymphopaenia (<1500/mm^3), thrombocytopaenia (<100,000/mm^3)
Immunologic disorder	Anti-DNA antibody to native DNA in abnormal titre; Anti-Sm, or positive finding of antiphospholipid antibodies based on an abnormal serum level of IgG or IgM anti-cardiolipin antibody or positive test for lupus anticoagulant or false-positive serological tests for syphilis
Antinuclear antibody	A significant titre by IF method in the absence of the other causes of positive ANA

A person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

A variety of disease activity indices such as SLEDAI, SLAM, BILAG, lupus nephritis activity index are available for research and clinical applications. To assess the degree of organ damage, damage indices (SLICC/ACR damage index, lupus nephritis chronicity index) have been developed.

Table 7: Investigations Depending on Systemic Involvement

System Involved	Tests
Renal	24 hours urinary protein and creatinine; Spot urine protein creatinine ratio; C3, C4, renal biopsy
Pulmonary	PFT with DLCO, HRCT, bronchoscopy with BAL fluid examination*
Cardiac	ECG, 2D echo with colour Doppler
Haematological	Coombs test, bone marrow examination, anti-platelet antibodies, antiphospholipid antibody
CNS	CSF examination, CT/MRI, PET/SPECT scanning, antiphospholipid antibody testing

** BAL fluid should always be submitted for microbiological studies.*

TREATMENT

The severity of SLE ranges from an almost inconsequential illness to a devastating illness with renal failure and profound nervous system disturbances. Because of this variability, therapy has to be individualised and determined by the disease severity and its manifestation(s) and not based on the primary diagnosis. Following guiding principles should be followed: (i) therapy should be directed at specific, active disease manifestations; (ii) the intensity of therapy should be based on severity of disease as assessed by objective measures; (iii) the therapy should be for the shortest period possible and at the lowest effective intensity to limit toxicity and side-effects; (iv) it is usually necessary to continue low dose prednisolone along with hydroxychloroquine on a long-term basis; (v) appropriate prophylactic measures against infections, osteoporosis, atherosclerosis are necessary; and (vi) Patients with active disease should be followed-up frequently.

Patient education is important as also allaying patient's fears and anxiety. Patients and their families need to be counselled about marriage, pregnancy, breastfeeding, precautions and preventive measures. Importance of proper diet, adequate rest and exercise to maintain fitness should be stressed.

Preventive measures include: (i) Protection from sunlight; (ii) prevention of infections (chemoprophylaxis, vaccinations); (iii) anti-osteoporosis measures (calcium and Vit. D supplementation, bisphosphonates are used in patients requiring prolonged steroid treatment); and (iv) prevention of IHD (control of BP, diabetes, lipids, and abstinence from cigarette smoking).

Specific therapeutic measures

Tables 8 and 9 summarise the drug treatment of active lupus. Manifestations, like depression and convulsions are treated by standard therapy.

PROGNOSIS

Over the years, prognosis of SLE patients has improved remarkably. Five and ten-year survival rates of 90% and 80%

Table 8: Drugs Commonly Used in the Management of SLE

Drug	Dose	Important Side Effects	Monitoring
NSAIDs	Depends on the NSAID	GI intolerance, GI bleed, hypersensitivity, exacerbation of renal impairment, rarely liver toxicity, aseptic meningitis	CBC, creatinine, SGPT once in 3 to 6 months and SOS
Chloroquine/ Hydroxychloroquine	2 mg/kg/day 4 to 6 mg/kg/day	Pruritus, nausea, and maculopathy	Eye check at the start of treatment and every 3-6 months for chloroquine and every 6-12 months for hydroxychloroquine
Dapsone	50 to 100 mg/day	Pigmentation, anaemia, psychosis	Exclude G6PD deficiency
Prednisolone*	0.25 to 1 mg/kg/day, initially in divided doses, later single morning dose, tapered subsequently to the lowest effective dose	Obesity, acne, diabetes, osteoporosis, infection, ischaemic heart disease, and avascular necrosis of bone	Regular BP, ocular pressure and blood sugar monitoring, bone density assessment in those on long-term treatment
Azathioprine*	1 to 2.5 mg/kg/day oral 15 mg/kg/pulse	Cytopaenias, pancreatitis	CBC on monthly basis (initially fortnightly x 2) and at every increment; amylase and lipase levels 3 monthly
Cyclophosphamide*	1 to 2 mg/kg/day	Nausea, vomiting, cytopaenias, infections, premature menopause, haemorrhagic cystitis, bladder cancer	Ensure adequate fluid intake; CBC on the 7th and 14th day if pulse therapy is given; urine routine examination
Mycophenolate Mofetil*	1 to 2 gm/day	GI disturbances, influenza-like syndrome, infections, cytopaenias	Periodic blood counts and blood chemistry

** Immunosuppressive drugs.*

have been reported from developed countries. In India 5- and 10-year survival rates of 68% and 50% have been reported. Renal failure and infection are the two main causes of death in Indian patients. Disease severity, delay in seeking as well as lack of access to medical help, inadequate and inappropriate treatment contribute to the higher mortality. Premature atherosclerosis and coronary artery disease are important causes of premature death. Though slight, there is a definite increased risk of cancer and haematologic malignancies in SLE patients.

SPECIAL PROBLEMS

Fertility, Pregnancy, Contraception

Fertility is normal, unless the disease is very active. Patients should be advised to plan pregnancy during periods of remission (when disease is quiescent and steroid requirement is 10 mg or less for 6-12 months). With active disease, there is an increased risk of spontaneous abortion and miscarriage, still-birth, premature birth and low birth weight (independent of APS). Other risk factors are anti-Ro antibodies, anticardiolipin antibodies and/or lupus anticoagulant, history of thromboembolism and foetal loss. These patients need close monitoring by a rheumatologist and an experienced obstetrician. The disease can flare during pregnancy. Steroids, hydroxychloroquine, and azathioprine can be continued during pregnancy. Cyclophosphamide, methotrexate, and mycophenolate should be discontinued 3 to 6 months before conception. Cyclophosphamide therapy carries the risk of age-dependent ovarian failure.

Intrauterine contraceptive devices should be avoided. Oestrogen-containing contraceptives should be avoided with APS. Contraceptives and post-menopausal hormone replacement therapy with progesterone-only pills are safe. Barrier methods can be practiced safely.

Paediatric and Neonatal Lupus

The clinical manifestations of SLE in the paediatric age group are essentially similar to those of adults. There is a higher frequency of lymphadenopathy, hepatosplenomegaly, nephritis, and avascular necrosis of the bone. SLE tends to be more severe. Principles of treatment are similar to that of adult SLE.

Table 9: Choice of Therapy in SLE

Symptom	NSAIDs	Anti-malarials	Steroids	IS#	IVIgG/ Biologics
Arthritis	Yes	Yes	• Yes	No	No
Fatigue	No	Yes	• No	No	No
Malar rash	No	Yes	• Yes	No	No
Serositis	Yes	No	• Yes	No	No
Pneumonitis	No	No	•• Yes	Yes	No

1. *Anti-coogulonts are indicoted for ontiphospholipid syndrome potients with thrombosis*
2. *Even though not specificolly indicoted for o particulor monifestation, anti-molorials should be given to oll SLE potients unless controindicoted or not toleroted since these hove multiple beneficiol effects*
3. *# Immunosuppressive theropy*
4. ** If stondord treotment foils*

Children born of mothers with SLE can develop neonatal lupus syndrome. Its manifestations include transient photosensitive discoid rash, cytopaenias, hepatosplenomegaly, myocarditis, and pericarditis. Treatment is symptomatic. Permanent features such as congenital complete heart block (CCHB), endomyocardial fibroelastosis, and other structural cardiac defects may occur. The risk of CCHB is related to anti-Ro antibodies. CCHB patients may need permanent pacemaker implantation in adulthood. Dexamethasone is given to mothers, to treat foetal CCF, pericarditis and heart block (diagnosed with foetal echocardiogram).

SLE in the Elderly

SLE in the elderly is often, but not necessarily, a milder disease. It is characterised by insidious onset, longer duration of disease at the time of presentation, and a lower incidence of renal, musculoskeletal, skin and neurological manifestations.

Infections

Patients with SLE are particularly susceptible to infections with intracellular organisms like *Candida*, Herpes, *Salmonella* and, *Mycobacteria* and capsulated organisms (*Pneumococcus, Meningococcus* and *H. influenzae*). The increased susceptibility is due to low complement levels, prednisolone (>20 mg/d), immunosuppressives (especially cyclophosphamide) and splenic hypofunction. Infection is often present along with active disease. When distinction between the two is difficult, both are treated simultaneously. Prevention of infection with chemoprophylaxis and vaccination is advised.

Drug-Induced SLE

The most commonly implicated drugs are listed in **Table 1**. Drug-induced SLE is uncommon in India. ANA, anti-histone antibodies, and LE cells are characteristic features of drug-induced SLE. The prevalence of drug-induced ANA is more common than the clinical syndrome. Clinical features are mild; renal and neurological involvement is rare. Symptoms resolve on withdrawal of the offending drug though the antibody titres may continue to remain elevated for a long time. Drugs known to induce SLE can be used to treat *de novo* SLE patients.

MCTD, Overlap Syndromes, Antiphospholipid Syndrome

These are discussed in separate chapters.

New and Experimental Therapies

Though the present therapies have significantly improved the prognosis of SLE patients, the results are far from satisfactory. Newer regimens and newer therapies are necessary. Dihydroepiandrosterone, a weak androgenic steroid, has shown moderate benefit in some studies. Newer biologic agents that target antigens, immune cells and other components of the immune response are promising newer therapies. Rituximab an anti CD 20+ (anti B cell) antibody is being used for treatment of refractory SLE. Belimumab is a totally human monoclonal antibody that inhibits B-lymphocyte stimulator (BLyS), also known as B-cell activation factor of the TNF family (BAFF). Belimumab is indicated for the treatment of adult patients with active, autoantibody-positive SLE who are receiving standard therapy. Recommended dosage regimens 10 mg/kg at 2-week intervals for the first 3 doses and at 4-week intervals thereafter by intravenous infusion. The efficacy of belimumab has not been evaluated in patients with severe active lupus nephritis or severe active central nervous system lupus. It has been recently approved for treatment of SLE. Autologous stem-cell transplantation has met with some success.

24.10 Antiphospholipid Syndrome

Vikas Agarwal

INTRODUCTION

The antiphospholipid syndrome (APS) is an acquired autoimmune disease characterised by thrombosis (arterial or venous) and/or pregnancy morbidity in the presence of a variety of circulating autoantibodies directed against the phospholipid-protein complexes. These autoantibodies are lupus anti-coagulant (LA), anti-cardiolipin (ACL) and antiβ2glycoprotein-1 (antiβ2GP1) antibodies. Diagnosis of APS can be relied upon in the absence of other causes of hypercoaguable state and persistent positivity for anti-phospholipid (APL) antibodies. APS may be primary (idiopathic) or secondary [in presence of disorders like systemic lupus erythematosus (SLE), rheumatoid arthritis, other connective tissue disorders]. The term 'anti-phospholipid' is misleading because the autoantibodies usually recognise complexes of proteins and phospholipids (PLs), not PLs alone.

EPIDEMIOLOGY

The exact prevalence of APS is not known; however, a female predominance has been described. About 30% of patients with LA and 30% to 50% of patients with moderate to high titres of ACL antibodies have clinical manifestations of APS. APS may account for 15% to 20% of all episodes of deep vein thrombosis, one-third of stroke below the age of 50 and 5% to 15% of recurrent foetal loss. In Indian setting, a prevalence of 27.7% has been reported in 155 females with recurrent miscarriages or late pregnancy loss from Kolkata and 40% from Tamil Nadu.

DIAGNOSIS

The revised criteria proposed in 2006 are outlined in **Table 1**. One clinical event and one laboratory abnormality are required to diagnose APS. Presence of APL antibodies is not equivalent to APS.

AETIOPATHOGENESIS

The predominant hypothesis regarding the origin of APL states that an incidental exposure to environmental agents with β2GP1-like peptides induces APL in susceptible individuals. The putative mechanisms of thrombosis include: (1) activation of endothelial cells by complexes of β2 GPI and anti-β2 GP1, (2) platelet activation after binding of the antiβ2 GPI by the activator receptor apo ER2067, (3) presence of autoantibodies against natural anti-coagulant proteins like annexin-5 and activated protein C, and (4) abnormal fibrinolysis. The mechanisms of pregnancy complications include: (1) APL binds to annexin-5 on the surface of the trophoblasts causing break in the anticoagulant shield of the placenta; and (2) an inflammatory reaction due to the activation of neutrophils, complement, and complement receptors is initiated leading to thrombosis.

Table 1: Revised Criteria for Diagnosis of Antiphospholipid Syndrome *(Miyakis et al, 2006)*

APS is present if at least one of the clinical criteria and one of the laboratory criteria are met*

Clinical Criteria

Vascular thrombosis

One or more clinical episodes of arterial, venous, or small vessel thrombosis in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e. unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

Pregnancy morbidity

One or more unexplained deaths of a morphologically normal foetus at or beyond the 10th week of gestation, with normal foetal morphology documented by ultrasound or by direct examination of the foetus; or

One or more premature births of a morphologically normal neonate before the 34th week of gestation because of: (i) eclampsia or severe pre-eclampsia, defined according to standard definitions, or (ii) recognised features of placental insufficiency; or

Three or more unexplained consecutive spontaneous miscarriages before the 10th week of gestation, with maternal anatomic or hormonal abnormalities, excluding paternal and maternal chromosomal causes.

Laboratory Criteria**

LA present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (Scientific Subcommittee on LAs/phospholipid-dependent antibodies).

ACL antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titre (i.e. >40 GPL or MPL, or >99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardised enzyme linked immunosorbent assay (ELISA).

Anti-β2 glycoprotein-1 antibody of IgG and/or IgM isotype in serum or plasma (in titre >99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardised ELISA, according to recommended procedures.

**Classification of APS should be ovoided if less than 12 weeks or more than 5 years separote the positive APL test ond the clinicol manifestations.*

***Investigotors are strongly advised to classify APS patients in studies into one of the following categories: I, more thon one laboratory criterio present (ony combination); IIa, LA present alone; IIb, ACL antibody present alone; IIc, onti-β2 glycoprotein-1 antibody present olone.*

Acute thrombotic microangiopathy with minimal or no inflammation is the pathologic hallmark. The chronic changes range from hypoperfusion to atrophy and fibrosis.

CLINICAL FEATURES

Arterial or Venous Thrombosis

The major clinical manifestation of the APS is thrombosis (either arterial or venous or both) confirmed objectively by either imaging or histpathologically. Arterial thrombosis occurs predominantly in the central nervous system (CNS), but may affect any segment of the arterial tree. It may present as myocardial infarction, aseptic osteonecrosis, adrenal insufficiency, or peripheral gangrene (**Figure 1**). Arterial thrombosis in younger people or people without obvious risk factors for thrombosis should alert to the possibility of APS. Venous thrombosis commonly localises to the deep veins of the lower limbs. It may be complicated by pulmonary embolism. However, any venous segment may be involved. Superficial venous thrombosis is not included in the classification criteria.

Figure 1: Gangrene of all the fingers of bilateral hands in a female with APS.

Pregnancy Morbidity

Persistent antiphospholipids (APLs) are seen in about 15% of women with recurrent miscarriage in the first or second trimester. In these women, the foetal loss rate can be up to 90% without pharmacological treatment. It may present as unexplained foetal death after the 10th week of gestation, or unexplained consecutive spontaneous miscarriages before the 10th week of gestation, or premature birth before the 34th week of gestation because of eclampsia or severe pre-eclampsia, not pre-eclampsia alone. The risk of pregnancy morbidity is unknown in asymptomatic APL-positive patients and in patients with APS with only vascular events.

Thrombocytopaenia

Thrombocytopaenia (platelets <150,000/μL) is seen in one-third of the patients; however, platelets are rarely low enough to cause bleeding. Other causes, such as (thrombotic thrombocytopaenic purpura (TTP), disseminated intravascular coagulation (DIC), and heparin-induced thrombocytopaenia should be excluded.

Autoimmune Haemolytic Anaemia

About 10% to 20% of the patients with APS may have positive Coombs' test, however, clinically significant autoimmune haemolytic anaemia (AIHA) is uncommon. It is usually associated with cardiac valvular lesions. Rarely, AIHA and thrombocytopaenia can occur simultaneously, referred as *Evan's syndrome*.

Neurologic Manifestations

Stroke and transient ischaemic attacks are the most common presentations. Other manifestations include cognitive dysfunction, dementia, chorea, transverse myelopathy, cerebral venous thrombosis, acute ischaemic optic neuropathy, central retinal artery occlusion, amaurosis fugax, sensorineural deafness, and epilepsy.

Cardiovascular Manifestations

It can present with intracardiac thrombosis or as valvular heart lesions (non-infectious Libman-Sacks endocarditis) affecting mainly the mitral valve. It is seen in 30% to 50% of the patients on Doppler echocardiography. Valve involvement is diffuse as compared to rheumatic heart disease (localised, involve leaflet margins, associated with thickening fusion and calcification of the chordae tendinae). Presence of endocarditis warrants prophylaxis against bacterial endocarditis but rarely requires valve replacement.

Skin Manifestations

The main skin manifestation of APS is livedo reticularis, seen in 25% of patients. Other manifestations are leg ulcers (**Figure 2**), cutaneous infarcts, gangrene, necrotising purpura and nailfold infarcts.

Figure 2: Ulcers involving the dorsum of feet and the legs in a young female with APS.

Renal Manifestations

Involvement of different vessels in the kidney may lead to variable presentation like hypertension, renal infarction, haematuria, and thrombotic microangiopathy. In patients with systemic lupus erythematosus, APS worsens the renal prognosis. Histologically, thrombotic microangiopathy and/or fibrous intimal hyperplasia, focal cortical atrophy, or tubular thyroidisation may be seen.

Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a rare complication with multiorgan failure secondary to widespread microvascular thrombosis. Kidneys are most commonly affected, followed by lungs, CNS and skin. Thrombocytopaenia and DIC are common laboratory findings. Catastrophic APS is initiated in 35% of the cases by a variety of infections. The mortality rate is up to 50%, due to multiorgan failure. It may mimic severe sepsis, TTP and DIC from any cause.

Two-thirds of survivors remain symptom free with anticoagulation during an average follow-up of 67.2 months. Recurrence may occur in 26% cases and a quarter of them may die.

LABORATORY DIAGNOSIS

The laboratory diagnostic criteria include ACL of IgM or IgG isotypes (moderate or high titres), LA and antiβ2GP1. LA is considered to be the best marker for the risk of thrombosis. The clinical abnormalities should be present on two or more occasions at least 12 weeks apart. The risk of thrombosis and pregnancy morbidity is higher in patients with multiple types of APL than in patients with a single APL positivity.

Antiphospholipid Assays

LA are antibodies that cause prolongation of APTT by blocking the phospholipid surfaces, (block assembly of prothrombinase, a complex of factors Xa, Va and prothrombin on a phospholipid template). This interferes with thrombin generation and slows fibrin formation. This is detected as prolongation of the clotting time in coagulation assays that include phospholipid. Moreover, this prolongation is not corrected by addition of platelet-free (i.e. no anionic phospholipids) plasma but by addition of an excess of PLs. Interpretation of the test is difficult in the presence of therapy with unfractionated heparin or with high-intensity oral anticoagulants (INR >3.5).

MANAGEMENT

Venous Thrombosis and Thromboembolism

The initial treatment of venous thrombosis is the similar to any other venous thrombosis. Treatment with intravenous unfractionated heparin or low molecular-weight heparin should be started, and vitamin K antagonist therapy should be initiated with the target INR of 2 to 3. Because of high risk of recurrence of thrombosis, lifelong anticoagulation is usually recommended. If anticoagulation is discontinued, the incidence of recurrence is highest during the first 6 months after discontinuation, and the recurrence will usually occur in the same type of vessel (venous or arterial, depending on the initial manifestation). Serial testing for APL is not useful and there is no consensus regarding discontinuation of anticoagulation in patients who have normalised APL levels.

Arterial Thrombosis

The majority of these patients will be diagnosed with a non-cardioembolic transient ischaemic attack or a stroke. Non-cardioembolic arterial thrombosis during APS should be treated with low dose aspirin. The treatment of non-cerebral arterial thrombosis is not clear; however, patients with myocardial infarction should receive long-term anticoagulation. Arterial embolism, mainly originating from the non-bacterial endocarditis, should be treated with long-term oral anticoagulation to avoid the accumulation of cerebral infarctions.

Pregnancy Complications

Women with history of pregnancy losses should be treated with subcutaneous unfractionated heparin (5000 units twice a day) plus low-dose aspirin or prophylactic doses of low-molecular-weight heparin (to reach an anti-factor Xa level of 0.1-0.3 U/mL) in combination with aspirin. Aspirin should be started at around the time of conception, and heparin as soon as the pregnancy is confirmed until the third trimester.

Catastrophic APS

It should be managed aggressively with heparin, plasmapheresis, intravenous immunoglobulin and high-dose glucocorticoids.

24.11 Systemic Sclerosis

R Porkodi, S Rajesh

Systemic sclerosis is a chronic autoimmune disease characterised by thickening and fibrosis of the skin. Internal organs like heart, lungs, kidneys and gastrointestinal tracts are often involved. Systemic sclerosis is 3-4 times more common in women than men and occurs between 30 and 50 years of age. Localised forms of scleroderma include morphea, linear scleroderma or facial hemiatrophy (en coup de sabre).

CLASSIFICATION

The classification is based on the extent of skin involvement:

(a) *Diffuse cutaneous scleroderma:* Skin thickening present on the trunk, face, proximal and distal extremities.

(b) *Limited cutaneous scleroderma:* Skin thickening limited to sites distal to the elbows and knees, may involve face and neck. CREST syndrome, a variant seen in some patients, comprises of calcinosis, Raynaud's, oesophageal dysmotility, sclerodactyly and telangiectasia.

(c) *Sine scleroderma:* Internal organ manifestations, vascular and serologic abnormalities, without detectable skin changes.

(d) *Overlap syndrome:* Any of the above occurring concomitantly with a diagnosis of systemic lupus erythematosus, inflammatory muscle disease or rheumatoid arthritis.

The differences between limited and diffuse systemic sclerosis are outlined in **Table 1**.

Table 1: Differences between Limited and Diffuse Cutaneous Scleroderma

S. No.	Limited Scleroderma	Diffuse Scleroderma
1.	Raynaud's predates the skin by several years	Raynaud's occurs usually within one year of onset of skin changes
2.	Skin involvement over the face, neck distal to elbows and knees, calcinosis, telangiectasia	Skin involvement over the face, neck, trunk, extremities
	Slow progression	Rapid progression with oedema of hands and legs
3.	Infrequent systemic symptoms, mild arthralgia, dyspnoea	Severe arthralgia, tendon friction rubs, internal organ involvement
4.	Oesophageal dysmotility, dysphagia	Severe intestinal problems and oesophageal involvement
5.	Occasional pulmonary fibrosis	Severe pulmonary fibrosis
6.	Severe pulmonary artery hypertension (PAH)	Cardiomyopathy, arrhythmia, secondary pulmonary hypertension
7.	No renal involvement	Renal crisis
8.	Anticentromere antibodies	Anti Scl-70 (topoisomerase 1 antibodies)
		Anti RNA polymerase III

AETIOPATHOGENESIS

Genetic factors: Linkage of the disease with HLA A1, B8 and DR3 haplotype or with DR3/DR52 has been reported.

Environmental factors: Exposure to silica, polyvinyl chloride, drugs like L-5- hydroxyl tryptophan, bleomycin, pentazocine and cocaine can predispose to scleroderma.

Infectious agents: Cytomegalovirus, Epstein Barr virus infections may play a role due to molecular mimicry.

There is interplay between genetic and environmental factors and autoimmunity (**Figure 1**). Vascular and immunological changes lead to fibroblast proliferation with collagen accumulation in a genetically predisposed individual when exposed to environmental triggers.

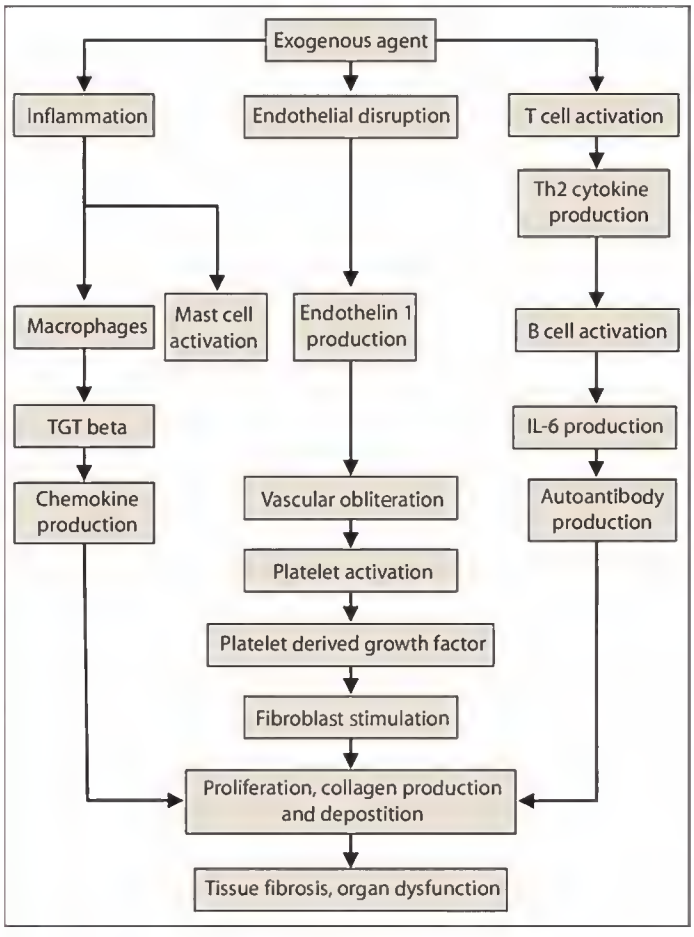

Figure 1: Pathogenesis of systemic sclerosis.

CLINICAL FEATURES

Raynaud's phenomenon is a forerunner of systemic sclerosis. Digital vessels show marked intimal hyperplasia due to collagen deposition and adventitial fibrosis. Vasoconstrictor response to cold or emotional stimuli leads to near complete occlusion of the vessel. Scleroderma renal crisis and pulmonary hypertension are the result of Raynaud's of internal organs. There is

loss of digital pulp-acro-osteolysis on radiographs (**Figure 2**) and pitting scars over the fingertips (**Figure 3**).

Figure 2: Radiograph of hands showing resorption of terminal phalanges.

Figure 3: Pitting scars over finger tips.

Skin

Pitting oedema of the fingers, dorsum of hands, face, trunk and upper arms is a characteristic feature of early scleroderma. Skin thickening of the fingers and hands (**Figure 4**) is followed by involvement of face and neck. Lips become thin and pursed, radial furrows appear around the mouth, giving a pinched appearance (**Figure 5**). Skin tightening leads to restricted mouth opening. Hair growth is sparse, salt and pepper like appearance with hypo- and hyperpigmented changes are seen (**Figure 6**).

Figure 4: Skin thickening of fingers and hands with contracture formation.

Figure 5: Pinched up facies.

Figure 6: Salt and pepper appearance.

Musculoskeletal Features

Significant arthralgia with morning stiffness is characteristic. Mild synovitis is seen in about half of these patients, erosions occur in 29%. Leathery tendon friction rubs can be palpated and auscultated with the movements of the tendons.

Muscle weakness may be secondary to disuse atrophy or there may be a mild proximal muscle weakness with mild muscle enzyme elevation and electromyographic (EMG) abnormalities like increased polyphasic potentials, decreased amplitude and duration.

Subcutaneous calcification over the fingers, olecranon and prepatellar bursae is seen in 40% of patients with limited cutaneous scleroderma.

Gastrointestinal Involvement

Oesophageal dysmotility leads to dysphagia; lax lower oesophageal sphincter causes heartburn due to reflux. 'Watermelon stomach' is characteristic due to gastric antral venous ectasia. Telangiectasia can lead to gastrointestinal (GI) bleed. Feeling of satiety, intermittent bloating, abdominal cramps, chronic diarrhoea, constipation, obstipation, pseudo-obstruction, wide mouthed diverticula, rectal prolapse and faecal incontinence are other features of GI involvement.

Pulmonary Manifestations

Pulmonary fibrosis and secondary pulmonary hypertension may be seen in diffuse variety. Pulmonary hypertension may also be present in absence of pulmonary fibrosis, especially in limited cutaneous scleroderma. Progressive exertional dyspnoea and nonproductive cough are typical features of pulmonary fibrosis. Physical findings include early inspiratory crackling rales. Usual interstitial pneumonitis (UIP), nonspecific interstitial pneumonitis (NSIP), bronchiolitis obliterans and diffuse fibrosing alveolitis are the different pathological variants. Impaired DLCO (diffusion lung capacity for carbon monoxide) and structural abnormalities on high resolution CT chest – like ground glass appearance may be seen even in asymptomatic patients (**Figures 7A and B**).

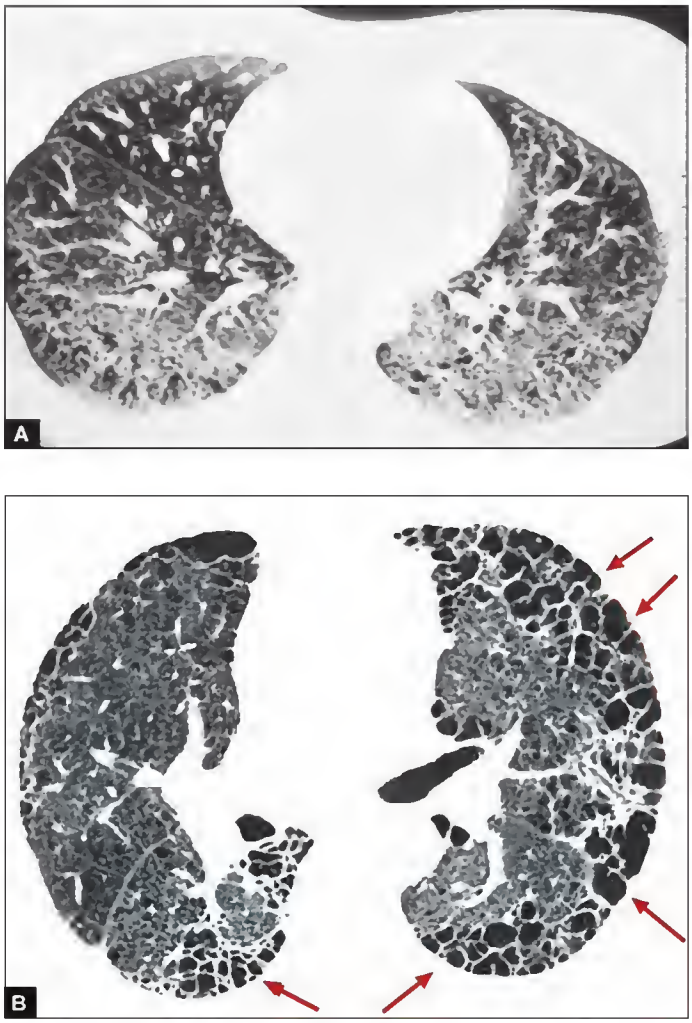
Pulmonary artery hypertension (PAH) is defined as a mean pulmonary artery pressure > 25 mmHg at rest and above 30 mmHg during exercise. PAH is a cause for the mortality and presents with exertional dyspnoea, fatigue, palpitation, chest pain, syncope and cough. Loud P2, right ventricular gallops, murmurs of pulmonary, tricuspid regurgitation, jugulovenous distension, hepatojugular reflux, leg oedema are the clinical features.

Cardiac Involvement

Patchy myocardial fibrosis leads to contraction band necrosis. This is due to ischaemia reperfusion injury. This can result in arrhythmia, cardiomyopathy with diastolic dysfunction. Pericarditis and pericardial effusion may also be seen.

Renal Involvement

Scleroderma renal crisis (SRC) occurs in 10% patients with diffuse scleroderma. Patients treated with high dose glucocorticoids are at the greatest risk. It is characterised by sudden onset of malignant hypertension, renal failure, haemolytic anaemia, proteinuria, microscopic haematuria and schistocytes on peripheral blood.



Other Symptoms

Sicca complex occurs in 20% to 30% of patients. Thyroid gland fibrosis can lead to hypothyroidism. Neuropathic pain due to trigeminal neuralgia or carpal tunnel syndrome can be present.

Pregnancy does not worsen scleroderma, though intrauterine growth retardation and low birth weight have been reported. Erectile dysfunction can occur in men.

Malignancy

Relative risk of lung cancer in scleroderma was 16.5 in one series.

Figures 7A and B: HRCT images of ground glass opacity and honeycombing of the lungs (arrows).

DIAGNOSIS

The diagnosis is clinicoserologic. Skin biopsy helps by demonstrating subcutaneous deposition of collagen, loss of hair follicles, sweat glands and inflammatory cell infiltrates in the early stages. The autoantibodies present in scleroderma are listed in **Table 2**.

Table 2: Autoantibodies in Systemic Sclerosis

Autoantibody	%	Association
ANA	90	—
Anticentromere Antibody	22 to 36	Limited cutaneous/CREST
Anti Scl 70 (topoisomerase I)	20 to 40	Diffuse cutaneous, lung fibrosis
RNA polymerase I and III	4 to 23	Diffuse cut, SRC, cardiac involvement
Antifibrillarin	6 to 8	Diffuse cut, ILD, PAH, renal crisis
Anti PM/Scl	2 to 5	Overlap with myositis
Anti Th/To	4 to 16	Limited cutaneous

Radiographs of chest for pulmonary involvement, of hands for resorption of terminal phalanges, calcinosis cutis can be done. HRCT chest, pulmonary function tests like DLCO will help in establishing early interstitial lung disease (ILD). Echocardiography will determine the pulmonary hypertension. Bronchoalveolar lavage fluid evaluation for the nature of cells—

eosinophils or neutrophils will indicate inflammation. Barium study and oesophageal gastric endoscopy will be useful. Nailfold capillaroscopy (**Figure 8**) shows dropouts and dilated capillary loops.

Figure 8: Nailfold capillaroscopy showing capillary dropout and dilated capillary loops.

DIFFERENTIAL DIAGNOSIS

Table 3: Differential Diagnosis of Systemic Sclerosis

Disorders characterised by or associated with skin thickening on the fingers and hands
Digital sclerosis of diabetes mellitus
Chronic reflex sympathetic dystrophy
Mycosis fungoides
Vinyl chloride disease
Amyloidosis
Acrodermatitis chronic atrophicans
Adult coeliac disease
Disorders characterised by or associated with generalised skin thickening, but sparing fingers and hands
Scleroderma adultorum of Buschke
Scleromyxoedema
Eosinophilic fasciitis
Eosinophilia-myalgia syndrome
Generalised subcutaneous morphoea
Porphyria cutanea tarda
Amyloidosis
Human graft versus host disease

TREATMENT

Management is based on symptoms and is organ specific. It has to be individualised.

Management of Raynaud's

Avoidance of cold temperature and keeping the hands and feet warm is helpful. Vasodilators like calcium channel blockers—Nifedipine (30 to 180 mg/d), amlodipine (5 to 20 mg/d), diltiazem, 5 HT antagonists like fluoxetine (20 mg/d), ACE inhibitors like enalapril (5 to 10 mg/d), losartan (50 mg/d) and parenteral vasodilators like iloprost (0.5 to 2 ng/kg/min) have been tried. Endothelial receptor antagonist - bosentan; phosphodiesterase inhibitors—sildenafil, tadalafil, vardenafil; anti-coagulants and surgical sympathectomy are also useful.

Pulmonary Hypertension

Drugs used in Raynaud's are also helpful in managing PAH-calcium channel blockers, bosentan (62.5 to 125 mg bid), sildenafil (50 mg bid-tid), prostanoids—epoprostenol (2 ng/kg/min), treprostinil and iloprost. Other agents used include digoxin, anti-coagulants, spironolactone and long-term low dose oxygen.

Gastrointestinal Disease

Metoclopramide (10 mg tid-qid) enhances gastrointestinal motility. Proton pump inhibitors like omeprazole are helpful in reflux oesophagitis. Frequent diarrhoea due to bacterial overgrowth is treated with antibiotics.

Interstitial Lung Disease

Corticosteroids and cyclophosphamide are widely used. Daily oral cyclophosphamide 100 mg/day or monthly intravenous cyclophosphamide (600 mg to 750 mg/m^2) are employed.

Scleroderma Renal Crisis

Prompt institution of ACE inhibitors is needed to control blood pressure. Angiotensin II receptor blocker like losartan is also beneficial.

Glucocorticoids are indicated in early oedematous phase of scleroderma, in severe arthritis, myositis, tenosynovitis, pericarditis and ILD. Steroids are used in low dose for the fear of precipitating scleroderma renal crisis.

Other Drugs

NSAIDs are used for arthritis. Methotrexate has been shown to be useful for skin involvement and arthritis. Mycophenolate mofetil has shown beneficial results for skin and ILD. A variety of other agents have been used with variable results. These include D penicillamine, cyclosporine recombinant IFN gamma, IFN alpha, halofuginone, recombinant human relaxin, minocycline, antithymocyte globulin and intravenous immunoglobulins. Immunoablation with autologous peripheral stem cell rescue and photopheresis have been tried. Other drugs under investigation include imatinib (200 mg/d), rituximab, alefacept and drugs targeting TGF-beta.

PROGNOSIS

Scleroderma is treatable, not curable. Limited cutaneous scleroderma has a good prognosis as it is a slowly progressive disease and skin thickening may improve because of atrophy. Diffuse cutaneous scleroderma may have a rapidly progressive course and median survival after the onset of significant pulmonary fibrosis, PAH or scleroderma renal crisis is usually less than five years.

24.12 The Vasculitides

Pradeep Bambery

INTRODUCTION

Vasculitis literally means inflammation of blood vessels. At histology, capillaries, small, medium or large vessels, of both the arterial and venous systems, demonstrate a spectrum of lesions including inflammatory cell infiltration, occlusion, granulomatous reactions and vessel necrosis (**Figure 1**). The tissues where these changes occur, display abnormalities consequent to ischaemia, haemorrhage and necrosis. Clinically, however, these translate into a large, heterogeneous, often bewildering, group of disorders with many causes, characterised by a wide diversity of symptoms, signs (**Figure 2**), extent of involvement, clinical behaviour and outcome.

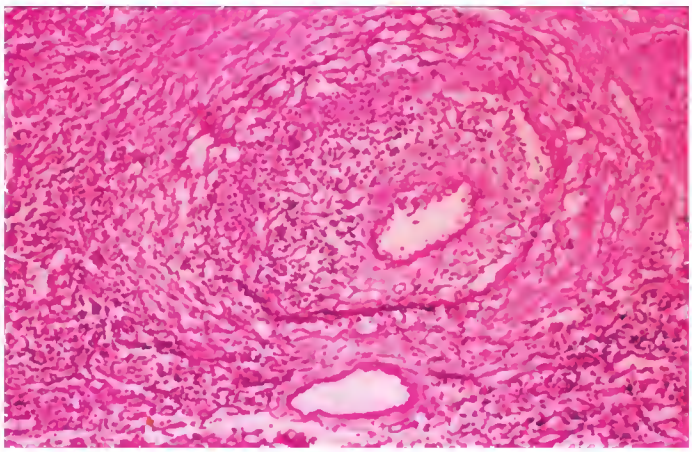

Figure 1: Vessel wall necrosis, luminal compromise, intense inflammatory cell infiltration, nuclear dusting and signs of tissue necrosis at the periphery. Classic appearance of vasculitis. Ill-formed giant cell granulomatous response is seen in the vessel wall.

Figure 2: Typical saddle nose deformity in a patient with Wegener's granulomatosis.

Clinically, however, the problem lies in thinking about vasculitis as a possible cause for the patients' problems. This is vital to force appropriate investigation leading to diagnosis and beneficial therapy. The vasculitides are uncommon disorders with largely non-specific manifestations that could mimic common, relatively benign conditions. Most patients with serious vasculitis however, give the physician clear clues and time to make a diagnosis. This is the challenge this chapter will hope to address. The possibility of successful outcome of therapy for even the most severely afflicted should go far in dispelling the perceptions of doom commonly associated with such a diagnosis.

EPIDEMIOLOGY

Reliable epidemiologic data from India is not available. Takayasu's arteritis is the commonest vasculitis described. Temporal arteritis is extremely uncommon. A significant number of patients with Wegener's granulomatosis have been reported in North India, it is relatively rare in the South. Classic polyarteritis nodosa has been well described. The incidence of systemic primary vasculitis in the Western world is around 20 per million per year. Significant geographic and ethnic variations have been noted.

CLASSIFICATION

The causes of vasculitis are listed in **Table 1**. Primary vasculitis has a presumed immune origin. If it is associated with any of the other causes, it is termed secondary (**Tables 2 and 3**). Several drugs cause vasculitis. Some of them are even anti-neutrophil cytoplasmic antibodies (ANCA) positive (**Table 4**). There are several conditions that successfully mimic vasculitis. They need to be excluded before a diagnosis is established (**Table 5**).

Table 1: Causes of Vasculitis

Immune mechanisms (idiopathic, related to recognised clinical syndromes)
Infections (bacterial, fungal, rickettsial, viral)
Drugs
Tumours
Radiation
Extremes of temperature

Classification has been a vexed, but dynamic, issue dependent on prevalent understanding of pathogenesis. Initially, it merely listed individual disease entities. It now incorporates pathology and, more recently, ANCA serology as well. The Chapel Hill Consensus Conference (CHCC) attempted to define primary vasculitides clinically as well as pathologically based entirely on vessel size (**Table 2**). As it only addressed the primary vasculitides, a sizeable part of the actual clinical spectrum was excluded. Lie attempted a wider, modified classification incorporating the entire clinical spectrum of the vasculitic disorders (**Table 2**). His classification was more flexible with

vessel size, clinically inclusive and reflected both clinical and necropsy observations. The pathologic basis of classification of primary vasculitides was further simplified by Savage (Table 3). Clearly, this remains 'work in progress'. Table 6 lists an example based on vessel size, ANCA, immune mechanisms and infectious mimics.

Table 2: Classification of the Vasculitides. Chapel Hill Classification (1993), The Current 'Gold Standard'

Chapel Hill Consensus Conference Classification 1993

Large vessel vasculitis:
- Giant cell arteritis, Takayasu disease

Medium vessel vasculitis:
- Polyarteritis nodosa (PAN), Kawasaki's disease

Small vessel vasculitis:
- Microscopic polyangiitis (MPA), Wegener's granulomatosis (WG), Churg-Strauss syndrome (CSS), Henoch-Schönlein purpura (HSP), essential mixed cryoglobulinaemia (EMC), cutaneous leucocytoclastic vasculitis

Classification of vasculitis (Lie 1994)

Primary vasculitis:
- Vasculitis of large, medium and small vessels
  - Giant cell arteritis, Takayasu disease
  - Isolated angiitis of CNS
- Vasculitis of medium and small vessels
  - PAN, CSS, WG
- Vasculitis of small vessels
  - MPA, HSP, cutaneous leucocytoclastic vasculitis
- Miscellaneous
  - Buerger's, Behcet's, Cogan's, Goodpasture's, and Kawasaki's syndromes

Secondary vasculitis:
- Infection
- Connective tissue diseases
- Drug hypersensitivity
- Essential mixed cryoglobulinaemia
- Malignancy
- Hypocomplementaemia
- Post-organ transplant

Table 3: Histopathologic Classification of Primary Vasculitis (Savage 1997)

Dominant Vessel Size	Granulomatous Pathology	Non-Granulomatous Pathology
Large	Temporal arteritis, Takayasu's arteritis	
Medium		Classic PAN, Kawasaki's disease
Small	Wegener's granulomatosis Churg-Strauss syndrome	Microscopic polyangiitis, HSP, EMC

CLINICAL MANIFESTATIONS

Although the vasculitides are truly 'multisystem' diseases, each entity has a predilection for certain organs and systems (Table 7).

General Symptomatology

Patients often have fever, weight loss, malaise, fatigue, night sweats, anaemia, generalised aches and feel unwell. Polymyalgia rheumatica, a syndrome that includes many of these symptoms is a 'red flag' suggesting vasculitis, and is frequently observed in temporal arteritis.

Table 4: Drugs Causing Vasculitis including ANCA Positive Vasculitis

Antibiotics	Macrolides, aminoglycosides, quinolones, sulphonamides, tetracyclines, penicillins, INH, rifampicin
Anti-thyroid	Propylthiouracil
Anti-convulsants	Phenytoin, carbamazepine, valproate
Anti-hypertensives	Hydralazine, methyldopa, nifedipine, atenolol, captopril, diltiazem, frusemide
Anti-arrhythmics	Quinidine, procainamide
Anti-coagulants	Heparin, warfarin, streptokinase
Vaccines	Hepatitis A, B, influenza, rubella, small pox
Interferons	Alpha, beta, gamma
Growth factors	G-CSF, GM-CSF
Leukotriene inhibitors	
Anti-metabolites	Allopurinol, colchicine, retinoids, alkylating agents, methotrexate, cytosine arabinoside
Psychoactive	Anti-depressants, cocaine, ecstasy
ANCA-positive drug-induced vasculitis	Hydralazine, propylthiouracil, leukotriene inhibitors, ciprofloxacin, minocycline, phenytoin, clozapine, sulphasalazine, allopurinol, D-penicillamine

Table 5: Conditions that Mimic Vasculitis and Need to be Excluded before Therapy is Started

Infections	Infective endocarditis, staphylococcal sepsis, nisserial sepsis tuberculosis, syphilis, invasive fungal infection, aspergillosis, mucormycosis, rickettsial infection, viral infection. HIV, CMV, VZV, parvovirus B19.
Drug-induced vasculitis	Ergot alkaloids
Cholesterol embolus disease	
Antiphospholipid syndrome	
Malignancy	Hairy cell leukaemia, carcinomas
Atrial myxoma	

The Skin

The skin is commonly involved. Many cutaneous vasculitides are, however, benign, self-limiting conditions confined to the skin and responsive to simple measures. However, the same clinical manifestations may also indicate the presence of a far more sinister, systemic necrotising vasculitis (SNV). The most common specific dermal lesion is palpable purpura. It develops most frequently near the ankle consisting of pinhead size, non-blanchable, red lesions from extravasated RBCs. Thrombocytopaenic purpura, of any causation, is, on the other hand, not palpable. Another fairly specific lesion is 'livedo reticularis', a reticulate pattern of skin vascularity delineated by small and medium vessel involvement. Other lesions include nodules and plaques that may, or may not, ulcerate, infarcts, ulcers, pyoderma gangrenosum, widespread skin necrosis and gangrene (Figure 3). Skin biopsy, from the edge of the lesion, is often very helpful in establishing a diagnosis.

Figure 3: Late in the process. Vasculitic lesions and early gangrenous changes are obvious.

Skin histology, however, is a poor predictor of clinical course. Several other skin lesions including macules, papules, vesicles, blisters and small bullae have been described in patients with vasculitis. Urticarial wheals are a feature of hypocomplimentaemic vasculitis, a benign disorder confined to the skin.

Muscles and Joints

Arthralgia, arthritis, (indistinguishable from rheumatoid arthritis) myalgia and weakness (like in polymyositis) are common non-specific complaints. Biopsy from involved muscles has a high yield for histologic confirmation of the diagnosis. Jaw claudication during mastication, is an important 'red flag' symptom in temporal arteritis.

Eyes, Ear, Nose and Throat

Scleritis, especially involving the perilimbic area (**Figure 4**), ring ulceration with corneal melt, scleromalacia, perforation of the globe, uveitis and retinal vasculitis are the usual ocular abnormalities. Recurrent otitis media often unresponsive to grommet insertion, hearing loss, perforation of the drum, recurrent, recalcitrant sinusitis, nasal septal perforation, a collapsed bridge of the nose, and severe oral ulceration are other manifestations.

Figure 4: Severe scleritis in a patient with vasculitis. Limbal ulceration is also seen in the picture.

Airways and Lungs

Trachea and bronchi are characteristically involved in Wegener's granulomatosis (WG) leading to stenosis, stridor and ventilatory compromise. Stridor is a 'red flag' symptom. Lung lesions include

Table 6: Aetiopathogenic Classification of the Vasculitides Incorporating the Modified CHCC Classification by Lie, Pathogenic Mechanisms and Infections

Dominant Vessel	Primary Vasculitis	Pathogenesis	Secondary Vasculitis	Pathogenesis	Infections
Large arteries	Giant cell arteritis Takayasu's arteritis	T-cell mediated	Aortitis of RA		*Staphylococcus*, *Salmonella*, Syphilis, *Aspergillus*, Mucor, Coccidiomycosis
Medium arteries	Classical polyarteritis nodosa	Immune complex related	Hepatitis B virus related PAN	Immune complex disease	*Streptococcus*, *Mycobacterium tuberculosis*, HBV, HCV, HIV, parvovirus B19
	Kawasaki's disease	Antibody-mediated hypersensitivity			
Small and medium vessel arteritis	Wegener's granulomatosis	Antibody-mediated (ANCA)	Vasculitis of RA, SLE, Sjögren's syndrome	Immune complex disease	*Streptococcus*, *Staphylococcus*, *Mycobacterium tuberculosis*, *Aspergillus*, Mucor, HBV, HCV, HIV, CMV
	Churg-Strauss syndrome	Atopic, hypersensitivity (ANCA)	Drug-induced		
	Microscopic polyangiitis	Antibody-mediated (ANCA)			
Small vessel vasculitis (leucocytoclastic)	Henoch-Schönlein purpura	Immune complex-mediated	Drug-induced		*Staphylococcus*, *Streptococcus*, *Salmonella*, *Mycobacterium*, *Yersinia*, *Nisseria*, *Rickettesial*, HIV, CMV, VZV, parvovirus B19
	Essential mixed cryoglobulinaemia	Immune complex-mediated			
	Cutaneous leucocytoclastic vasculitis				

Table 7: Clinical Features of the Major Vasculitides Encountered Clinically with Relative Frequency of each Area of Involvement

	Henoch-Schönlein Purpura	Microscopic Polyangiitis	Wegener's Granulomatosis	Churg-Strauss Syndrome	Classic Polyarteritis Nodosa
Purpura	4+	3+	1+	2+	Rare

GI tract	3+	2+	1+	2+	2+
Joints	3+	3+	3+	2+	2+

*1+ reported (< 10%), 2+ common (10-40%), 3+ very common (50-70%), 4+ almost invariable (> 70%); * not possible as per Chapel Hill definition.*

infiltrates, nodules, cavities, mass lesions, 'abscesses', areas of consolidation and haemorrhage. Clinical features comprise of cough, chest pain, expectoration, haemoptysis and respiratory failure. Large pleural effusions are uncommon. Cavitating nodules are highly suggestive of vasculitis. Metastases and disseminated infection need to be excluded.

Heart

Pericardial and myocardial involvement is commonly seen at necropsy but is rarely of great clinical significance. Coronary arteritis leading to significant ischaemic injury is associated with Kawasaki's disease and classic polyarteritis nodosa.

Gastrointestinal Tract

Gastrointestinal manifestations are caused by bowel ischaemia. Symptoms range from mild abdominal angina to those of perforation and peritonitis. The later carry a grave prognosis. In a patient with established vasculitis and in those with an obscure multisystem disease, abdominal pain, emesis, intestinal obstruction and bleeding are important 'red flags' that warrant immediate investigation and treatment.

Haemobilia and hepatic infarction especially in polyarteritis nodosa (PAN), splenic infarcts, pancreatitis, and a syndrome resembling inflammatory bowel disease have been reported.

Kidneys

Renal lesions due to vasculitis are diverse. Large vessel disease results in ischaemia and renovascular hypertension. Medium vessel involvement leads to infarction and haematomas within and around the kidney while small vessel disease is associated with glomerulonephritis. This can vary from mild, focal or segmental disease to rapidly progressive, crescentic involvement leading to significant, often life-threatening, renal failure. Glomerular lesions may show immune complex deposition or could be pauci-immune as in the ANCA associated vasculitides. In patients with suspected vasculitis, proteinuria, microscopic haematuria and active urinary sediment, in the absence of infection, should start alarm bells ringing for urgent management.

Reproductive Organs

Testicular infarction, presenting like torsion, is common in medium vessel vasculitis like PAN. Penile ulcers on the glans and shaft are uncommon but reported. These, and scrotal ulcers are, however, frequently seen in Behçet's syndrome.

Nervous System

Mononeuritis multiplex and polyneuritis cranialis are the most important 'red flags' suggesting a vasculitic process. Diffuse brain dysfunction is possible consequent to metabolic disturbances like renal and respiratory failure or sepsis.

CLINICAL SUSPICION

Acute progressive palpable purpura, ulcerating nodules and plaques, skin infarction or necrosis, and impending gangrene of unidentifiable cause, all suggest systemic vasculitis which must be investigated (**Tables 8 and 9**) and treated expeditiously (**Table 10**). These lesions are an important warning to physicians at the onset and relapse of SNV.

In patients without skin involvement, diagnosing SNV can be difficult. A high index of suspicion is essential to link apparently unrelated, seemingly unimportant and unexplained manifestations together. Chronic unresolving sinusitis, obstinate otitis media, recurrent or poorly responsive scleritis, severe constitutional symptoms without specific laboratory abnormalities, pulmonary 'tubercular' infiltrates unresponsive to adequate antitubercular drug therapy, non-resolving pneumonia despite adequate antibiotic therapy, abdominal angina in a young person, unexplained gastrointestinal bleeding, failure to recover from a 'successful' appendectomy, testicular 'torsion' in a young hypertensive, unexplained haematuria, and all the 'red flags' mentioned above should prompt the question 'Could this be a systemic vasculitis?' (**Table 11**).

If more than one system is involved, (e.g. otitis media in a patient with 'pulmonary TB', abdominal pain and mononeuritis multiplex in a young hypertensive) it is easy to answer in the affirmative. However, even when only one system is involved, a less than optimal response to standard therapy should be enough to start investigating along these lines. In desperately ill patients with an unexplained, rapidly progressive, systemic disease, it is justifiable to initiate life-saving treatment after eliminating sepsis.

INVESTIGATION

Investigations are listed in Table 8.

Table 8: Essential Investigation for Patients with Suspected Systemic Vasculitis

Haematology	Hb, TLC, DLC, platelet count, ESR (preferably Westergren method)
Biochemistry	Renal and hepatic function, serum albumin, globulin, alk. Phosphatase, CRP (quantitative) or other acute phase reactants*
Urine	Protein, microscopy and culture
Microbial	Blood culture, cultures for fungi*
Serology	ANCA, RF, ANA, hepatitis B and C, cryoglobulins, GBM*
Imaging	Chest radiograph, CT of head, chest and abdomen*, angiogram*, echocardiogram
Histology	Biopsy from involved area essential to confirm diagnosis

**Denotes tests that may be indicted in some, but not for all, patients.*

Routine

Systemic inflammation, the hallmark of SNV, can be established by an elevated ESR, leucocytosis, thrombocytosis, normocytic, normochromic anaemia, hypoalbuminaemia, hyperglobulinaemia and elevated acute phase reactants like CRP. Urine analysis and microscopy help establishing renal involvement. Appropriate culture to exclude infection must be done.

Serology

Serologic tests help in distinguishing between primary and secondary vasculitis. Rheumatoid factor (RF) is frequently positive in patients with vasculitis. High titres are, however, a hallmark of systemic rheumatoid vasculitis.

Anti-nuclear antibodies (ANA) are present in high titres in patients with systemic lupus erythematosus (SLE), systemic sclerosis (SSc), Sjögren's syndrome (SS) and other overlap syndromes. When these conditions are responsible for vasculitis, a positive ANA, contributes significantly to the correct diagnosis. Positive tests for Hepatitis B and Hepatitis C virus help in the diagnosis of classic polyarteritis nodosa (cPAN) and cryoglobulinaemic vasculitis due to essential mixed cryoglobulinaemia (EMC). Anti-glomerular basement membrane (GBM) antibodies, in patients with the pulmonary renal syndrome, indicate Goodpasture's syndrome.

ANCA

Anti-neutrophil cytoplasmic antibodies (ANCA) have added a new dimension to the study, understanding and classification of the vasculitides (Table 9). Serum with ANCA produce three basic patterns at indirect immunofluorescence (IIF). The classic cytoplasmic, or C-ANCA, shows central, coarse, dense, granular fluorescence. Perinuclear, or P-ANCA, shows perinuclear fluorescence and atypical ANCA shows a mixed pattern. The antibody specificities and clinical correlation of each pattern are listed in Table 9.

ANCA testing, using IIF and ELISA, is essential in the investigation of all patients with presumed vasculitis. While ANCA is positive in high titres during the acute phase of the ANCA associated vasculitides, there is poor correlation between titres and clinical disease activity.

Table 9: Anti-neutrophil Cytoplasmic Antibodies (ANCA). Indications, Methods, Patterns, Antigens, Associations and Interpretation

Indications for testing

- Suspected systemic necrotising vasculitis
- Pulmonary renal syndromes
- Sub-glottic stenosis and tracheobronchial pathology
- Retro-orbital, nasal, paranasal sinus related mass/destruction
- Scleritis, scleromalacia, limbal inflammation, recurrent/unresponsive

Methods used

- Indirect immunofluorescence (IIF) using unstimulated, ethanol fixed human neutrophils for pattern
- ELISA for antibody specificity

Patterns and antigens

- C-ANCA coarse granular central fluorescence linked to anti-serine proteinase 3(PR3).
- P-ANCA perinuclear linked to anti-myeloperoxidase (MPO), lactoferrin, cathepsin G, elastase, defensins, azurocidin, BPI (bactericidal permeability increasing protein), lysozyme, etc. All neutophilic granular proteins with antimicrobial functions.

Associations

- C-ANCA (anti-PR3), WG (> 90% in active disease), MPA (about 10% in active disease), CSS (50-60% in active disease)
- P-ANCA, (anti-MPO), MPA (70-90% in active disease), WG (< 10% in active disease)
- P-ANCA and indeterminate staining ANCA, (non-MPO), inflammatory rheumatic diseases, RA, Felty's syndrome, SLE, juvenile arthritis, systemic sclerosis, inflammatory bowel disease, autoimmune hepatitis, crescentic glomerulonephritis, sepsis, infective endocarditis, malaria, tuberculosis, Hansen's disease, onchocercosis, bronchiectasis, cystic fibrosis, drug-induced vasculitis, lung cancer and other neoplasia

Interpretation

- C-ANCA with anti-PR3 in the clinical setting of WG is highly suggestive of WG
- C-ANCA with anti-PR3 is positive in only the rare patient with MPA
- P-ANCA with anti-MPO in the clinical setting of MPA is highly suggestive of MPA
- P-ANCA, non-MPO, is not diagnostic of any condition
- P-ANCA, anti-lactoferrin and anti-elastase in the appropriate setting support drug-induced vasculitis
- P-ANCA anti-cathepsin G and anti-lactoferrin in the appropriate setting support inflammatory bowel disease

Imaging

Clinical diversity precludes the development of a radiologic protocol suitable for all patients. A chest radiograph is essential and may show a variety of lesions. Nodular cavitating infiltrates are characteristic of WG. On serial examinations, they may also migrate. Unresolving or rapidly progressive consolidation during adequate antitubercular or antibiotic therapy, also suggests a vasculitis. Pulmonary haemorrhage (WG, MPA) manifests as a rapidly enlarging parenchymal lesion. Angiography, CT, MRI and PET scans help with diagnosis, delineation of disease extent, identification of a biopsy site and monitoring response to therapy.

Patients with large vessel vasculitis like Takayasu's need angiography to define the extent of disease, classify it and identify areas for intervention like angioplasty and stent insertion. Angiography may show the pathognomonic visceral aneurysms in PAN.

Histology

Histologic proof of vasculitis remains the gold standard. Every possible attempt should be made to identify and biopsy the involved tissue (**Figure 1**). Skin lesions are an obvious first choice. However, it must be emphasised that the same histologic findings may be observed in patients with benign cutaneous vasculitis and SNV.

If the kidneys are involved, renal biopsy is often helpful. While it is usually not possible to distinguish between WG and MPA based on renal glomerular histology alone, granulomatous inflammation, is present, supports WG.

In the presence of mononeuritis multiplex, a sural nerve biopsy may reveal vasculitis of the vasa nervosum. Similarly, mucosa of the sinuses and nose may be sampled if the area is involved. Biopsy from these sites is limited by the size of the sample that can be safely taken and many pieces may be needed to establish the diagnosis. Vasculitis is often a patchy process and may be completely missed in a small biopsy. Open lung biopsy is a safe and highly rewarding procedure in patients with obscure lung shadows. As relatively large samples can be taken, they provide excellent material for diagnosis.

Differential Diagnosis

The vasculitides have many mimics (**Table 5**). Their treatment is different hence, they need to be excluded.

Decision to Treat

While patients with benign cutaneous or a slowly progressive disease allow time for histologic confirmation, seriously ill patients do not. As these patients carry a high mortality risk, institution of therapy is of paramount importance. The five factor clinical score is an excellent simple objective measure of the gravity of the clinical situation. In patients with SNV, the presence of renal failure, proteinuria more than 1 gm/24 hours, gastrointestinal involvement, CNS manifestations or cardiomyopathy are each accorded a score of one. Over 2 years, patients with a total score of 0 had a mortality of 12%, those with 1, 26% and those with 2, 46%. Clearly, patients with visceral disease should receive prompt and aggressive treatment, frequently on empirical grounds. Infections are also common in such patients, before, during and after immunosuppressive therapy. Frequently, the two are inseparable and need to be treated simultaneously. The vasculitides and their mimics are frequent among patients presenting to the emergency departments. Diagnosis is delayed at survival peril. **Table 10** lists the problems that must raise the question of a possible vasculitis in this group.

TREATMENT (TABLE 11)

Vasculitis caused by infection should be treated with the appropriate antimicrobial agents and surgical intervention. Results are good if instituted early.

Benign cutaneous vasculitic conditions generally respond well to low dose steroids, antihistaminics to suppress itching, dapsone and exposure of ulcerated areas to ultraviolet light. The occasional unresponsive patient may be helped with azathioprine or methotrexate. It is very unusual for isolated cutaneous vasculitis to require aggressive immunosuppressive therapy.

Patients with SNV mandate the use of high dose corticosteroids, cytotoxic and other immunosuppressive agents (**Table 10**). The NIH protocol, the first successful treatment plan for these conditions, commenced with oral prednisolone (1 mg/kg/day) and cyclophosphamide (CYC) (2-3 mg/kg/day). Steroids were tapered off and stopped within 6 months, but CYC continued in the same dose for a year after remission was attained. Thereafter, it was tapered gradually. This treatment revolutionised the management of these conditions. Before its development, 5-year survival for SNV like WG was less than 5% to 7%. With treatment, it increased to 75% to 85%. Problems related to treatment, like haemorrhagic cystitis and bladder cancer due to CYC, marrow toxicity, a high relapse rate after withdrawal, and infection gradually emerged. The search for an ideal regimen has, thus, continued.

Table 10: Emergency Medicine, Presentations to the Emergency Department, Symptoms and Signs

Presentation	Organ/System Involved	Manifestations
Very acute	Lungs	Pulmonary haemorrhage, respiratory failure, anaemia, increased DLCO, bronchopneumonia
	Airways	Stridor due to tracheomalacia
	Kidneys	Acute, rapidly progressive renal failure, haematuria, infarction, accelerated hypertension
	Urinary/genital tract	Haematoma, ureteric obstruction, bladder neck obstruction, testicular infarction
	Nervous system	Mononeuritis multiplex, polyneuritis cranialis, infarction, stroke, retinal ischaemia
	GI Tract	Perforation and peritonitis, intestinal ischaemia, occasionally bleeding
	Heart	Acute coronary syndrome
	Liver and biliary tract	Infarction, haemobilia, pancreatitis
Acute	Lungs	Pulmonary nodules and infiltrates, consolidation, compromised airway
	Kidneys	Loin pain, haematuria, worsening renal function, proteinuria with active sediment
	Urinary/genital tract	Testicular pain, hydronephrosis, perirenal haematoma
	Nervous system	Focal neurologic defect
	GI Tract	Abdominal angina
Indolent with acute exacerbation	The patient	With polymyalgia rheumatica, red eye, chronic sinusitis, worsening or miraculously improved asthma, oral ulceration, new onset hypertension, fever, arthralgia, non-specific skin rash, with recent onset palpable purpura and other systemic features in permutations and combinations beg the question, 'Is this a vasculitis?'

Table 11: Management of Vasculitis with Risk and Extent Stratification (* = very rarely used)

Distribution	Progression	Involvement	Investigation	Eliminate	Initiate Therapy With	Therapy for Poor Response
Cutaneous	Slow	Skin alone	All listed + biopsy	All mimics	Steroids	Azathioprine, Methotrexate, Dapsone, Cyclophosphamide
Systemic	Slow	Skin, joints, polymyalgia ENT	All listed + biopsy	All mimics especially chronic infections	Steroids + Methotrexate	Azathioprine, Cyclophosphamide, Mycophenolate mofetil
Systemic	Slow initially, with acceleration	Above + Kidney, CNS GI tract, heart, lungs liver, spleen	All listed + biopsy if possible	All mimics especially Infections and tumours	There is a place for empirical therapy Steroids + Cyclophospha-mide ± Plasmapheresis	Azathioprine, Mycophenolate mofetil, Cyclosporin, biologic therapy
Systemic	Rapid	As above + Lung haemorrhage, rapidly progressive renal failure, focal CNS defect, Multiple organ/ system involvement, GI perforation	As much as possible	Infection	Empirical high dose IV methyl-prednisolone + IV Cyclophospha-mide ± Plasmapheresis and Antibiotics (if infection not clearly eliminated), ventilation, dialysis, ICU measures with monitoring of fluid therapy, electrolytes and organ/ system support Surgery (as indicated)	Addition of another drug like azathioprine may help some. Anti TNF therapy may be helpful. Rituximab has helped (Other useful agents are listed in text)

Currently, the use of intermittent 'pulse' CYC (750 mg/m^2) has gained ground. It is used every 2 to 3 weeks initially for 2 to 3 doses and then every 4 weeks till six 'pulses' have been administered. With steroids, this treatment is very successful in inducing a remission. This form of therapy also results in lower infection rates and a far lower cumulative dose of CYC to achieve remission. This should lead to reduced rates of secondary malignancy. Once remission is achieved, recent trials have established that they can be maintained using azathioprine or methotrexate.

Some forms of vasculitis have been shown to respond very well to specific interventions. Temporal arteritis is very responsive to corticosteroids. Infusions of immunoglobulins are very useful for Kawasaki's disease, while Behçet's disease responds to colchicine, azathioprine, cyclosporine and thalidomide. Patients with cryoglobulinaemia and hepatitis B related classic PAN respond well to plasmapheresis to achieve initial control and subsequently to antiviral drugs.

Several patients, however, do not respond to conventional therapy described above. Alternate regimens incorporating mycophenolate mofetil, deoxyspergualine, and several monoclonal antibodies have been tried with variable success. Patients with vasculitis, on treatment, need to be carefully monitored for side effects and complications of these toxic regimes. Those on CYC should be encouraged to drink plenty of water to avoid cystitis, and possibly cancer.

Further treatment depends on the demonstration of relapse. All patients with vasculitis and specially those with the life-threatening SNV need to be closely followed, preferably with objective systems of record keeping. The Birmingham Vasculitis Activity score is one such instrument that permits, on a single page, a comprehensive record of each clinic visit with a numerical expression of both improvement and deterioration.

IMPORTANT INDIVIDUAL VASCULITIDES

Large Vessel Vasculitis

Takayasu's arteritis

Takayasu's arteritis (TA) is relatively common in India while temporal arteritis is extremely rare. TA affects young people who present with symptoms and signs of ischaemia involving the ocular, cerebral, renovascular, cardiopulmonary, limb, and splanchnic circulation in various permutations and combinations. The disease is classified according to the angiographic pattern of aortic involvement. Very few patients present with acute vascular inflammation. Most of them present with established stenotic or rarely, aneurysmal lesions. The common clinical findings are absent pulses, asymmetric blood pressure measurements and vascular bruits. If present, tenderness over the involved vessels, specially the carotids (carotidynia) is an important sign of active disease. Treatment with immunosuppressive regimens suppresses active inflammation but has only marginal effect on vessel patency. Patients with critical stenosis require angioplasty with stent insertion or surgical revascularisation for relief from ischaemia.

Temporal arteritis

Giant cell arteritis (GCA) is a disease of older people characterised by headache, polymyalgia rheumatica, and a distended, tortuous, thickened and sometimes tender temporal artery. Jaw claudication is an important symptom and blinding serious retinal ischaemia develops in several patients. The ESR is often over 100 mm and ultrasonography of the artery is helpful in identifying areas of involvement. The disease usually responds very well to corticosteroids alone.

Medium and Small Vessel Vasculitis

Polyarteritis nodosa

Polyarteritis nodosa (PAN) is a disease of protean manifestation with involvement of several organ systems. There is a close association between hepatitis B virus infection and PAN, and it was also the first vasculitis which was successfully treated with antiviral drug therapy. Patients usually have a nondescript febrile illness with loss of weight and other constitutional symptoms. However, most patients develop additional features like hypertension, mono or polyneuropathy, testicular pain, myalgia, and muscle weakness and renal insufficiency. Some patients will develop signs and symptoms of intestinal obstruction/perforation, renal, hepatic and splenic infarction. Investigations are usually not very specific but angiography may demonstrate the almost pathognomonic micro-aneurysms. Only an occasional patient is ANCA positive. Treatment has made a great difference to the outcome. When no effective treatment was offered, the median survival was three months. Today, with the appropriate use of steroids and cytotoxic drugs, five years survival has increased to over 80%. Classic PAN is often a 'one shot' illness and relapses are less frequently observed than in other SNVs.

Churg-Strauss syndrome

This entity is also called allergic angiitis and granulomatosis. The dominant feature is asthma and eosinophilia. The asthma may be long standing or of relatively recent origin. At the start of the vasculitic phase, most patients complain of severe worsening and unresponsiveness of previously controlled asthma. However, in some patients asthma may almost vanish at the time vasculitis develops. Cardiac and skin involvement is common in this disorder. Histology reveals vasculitis and an extravascular eosinophilic granuloma. Significant renal involvement is rare compared to other systemic vasculitides. Most patients respond adequately to corticosteroids but a few may require cytotoxic drug therapy.

Wegener's granulomatosis

This entity shows very wide clinical variations. It is compatible with several years of survival at one end of its clinical spectrum and death within days at the other. The upper airways, lungs and kidneys are the most commonly involved areas; however, no organ system is consistently spared.

Patients may present with severe ocular inflammation including scleritis, uveitis, corneal ulceration, dacryocystitis, lid ulcers and proptosis. Ear involvement includes severe unresponsive otitis media, perforation of the drum, bleeding and deafness. Nasal manifestations include extensive crusting, discharge, bleeding, perforation of the septum and a saddle nose deformity. Pulmonary manifestations include cough, sputum production, haemoptysis and pulmonary haemorrhage. The chest radiograph may show infiltrates, nodules, cavities or consolidation. Renal involvement is in the form of pauci-immune focal, segmental or crescentic glomerulonephritis with or without renal failure.

In many patients, WG starts as an indolent, locally confined, inflammatory disease. This, 'granulomatous' phase may last from weeks to several years before the aggressive 'vasculitic' phase supervenes. In patients from northern European origin, a prolonged indolent phase enables the diagnosis to be made while the disease is confined to a single area. In India, however, it appears that this phase is abbreviated. Well over half of our patients presented with established widespread systemic involvement.

The clinical similarity with pulmonary tuberculosis has often delayed consideration of WG. A very large number of the patients with WG in India had, and continued to receive anti-tubercular drug therapy in spite of continued clinical deterioration. There are a few pointers that may help to distinguish between these two. Ocular, ear, paranasal sinus, and nose involvement as well as vasculitic skin involvement and renal insufficiency are very uncommon in patients with tuberculosis. The presence of any of these features should raise suspicion and a diagnosis of WG should be considered. Radiologically, the infiltrates in TB are usually apical and the cavities are in the upper zone. However, in WG, infiltrates and cavities are more in the middle and lower zones of the lung. The demonstration of C-ANCA is useful however, rare patients with TB are P-ANCA positive so, the testing must be done carefully.

WG is treated with a combination of steroid and cytotoxic drugs for variable duration depending upon the response. Given the possible complications of the disease and its treatment, such patients should be treated in a specialised unit with adequate experience. Untreated WG had a mean survival of a few months. Renal failure, apart from pulmonary haemorrhage and widespread vasculitis are the usual causes of death in the first year. Later, destructive pulmonary disease and respiratory failure become more important. With adequate therapy more than 90% of patients should achieve a clinical remission.

Systemic rheumatoid vasculitis

This complication develops in patients with longstanding seropositive rheumatoid arthritis and carries a poor prognosis. The usual manifestations include new or worsened constitutional symptoms, cutaneous leucocytoclastic vasculitis and mononeuritis multiplex. Treatment should include steroids and cytotoxic drugs.

Small Vessel Vasculitis

Microscopic polyangiitis

This disorder was initially considered to be a variant of PAN. It has now come to be recognised as an independent entity with closer similarity to WG. While its renal manifestations and alveolar haemorrhage are very similar to WG, its other manifestations, including involvement of the skin, the nerves, and GI tract resemble PAN. Serologically, 90% of patients are P-ANCA positive. There are no granulomata seen at histology.

The dominant clinical features are due to a pauci-immune glomerulonephritis. Other features include pulmonary haemorrhage, cutaneous vasculitis, mononeuritis, joint pains, hypertension, GI tract involvement and occasionally CNS involvement. The disease responds to immunosuppressive treatment protocols useful for WG.

Henoch-Schönlein purpura

This condition predominantly affects children and young adults. The typical presentation includes palpable purpuric skin lesions, GI tract involvement with bleeding, arthralgia and glomerulonephritis. In most instances, it is a self-limiting condition and does not require treatment. However, the presence of severe bowel involvement and other atypical features like focal neurologic deficit, pulmonary haemorrhage and rapidly progressive renal failure warrant steroid and/or cytotoxic drug therapy even though their efficacy has not yet been established in a clinical trial. These complications are more frequently observed in adult patients.

Cutaneous leucocytoclastic vasculitis

Vasculitis confined to the skin producing infarcts, nodules, ulcers and very occasionally, gangrene is common. These patients should be investigated for the presence of systemic disease and if found negative can be treated with low doses of steroids and immunomodulating agents like dapsone.

Behçet's syndrome

This vasculitic disease entity has a pronounced geographical distribution, from Turkey to Japan *via* Iran and also the northern part of India. It affects young people and is more virulent in males. The dominant clinical manifestations are of painful oral and genital ulcers, a variety of skin lesions, severe, vision threatening ocular inflammation, arthralgia, focal CNS dysfunction, aseptic meningitis, colonic ulceration, aneurysms and venous thrombosis. There is a strong association with HLA B51 and it is the leading cause of blindness in Japan. The course is relapsing and remitting. However, the intensity wanes with advancing age. A variety of agents have been found to be useful including steroids, cytotoxic drugs, cyclosporine, thalidomide, colchicine, antibiotics and anti-TNF therapy.

Kawasaki's disease

This, predominantly childhood, vasculitis has a strong affinity for the coronary arteries. Most patients are under 5 years of age. Fever, conjunctival congestion, inflamed oral mucosa, cervical non-suppurative lymphadenopathy and cutaneous manifestations are the major features. Immunoglobulins have been found to be very effective in treating this condition. Follow-up echocardiograms may reveal the development of coronary aneurysms.

Cogan's syndrome

Is a rare disease of young adults characterised by non-syphilitic interstitial keratitis, recurrent symptoms like Meniere's disease and large vessel vasculitis, frequently involving the aorta and its major branches. Other features include joint pain, fever, abdominal pain, intestinal bleeding, hepatosplenomegaly and lymphadenopathy. While ocular involvement may respond to topical steroids, ear involvement requires systemic treatment. Vasculitis requires aggressive immunosuppressive therapy as outlined above.

Primary angiitis of the central nervous system

It is a rare disorder characterised by focal, or occasionally diffuse, neurologic involvement, MRI abnormalities and characteristic angiographic appearances without any other systemic features. Biopsy reveals a granulomatous angiitis in many patients. Treatment with steroids and cyclophosphamide is successful if the diagnosis is made early.

THE CHALLENGE

Thinking that a vasculitis could be responsible for the patient's problems is the biggest hurdle we need to cross. Treatment is very rewarding but entails hard work. Due to the multi-system nature of these disorders, the development of a multi-disciplinary team greatly facilitates patient management.

RECOMMENDED READING

1. The Vasculitides, Section 11 in Hochberg MC, Silman AJ, Smolen JS, Weinblatt ME, Weisman MH (editors), Rheumatology; 3rd Ed. Mosby; 2003: pp 1583-715.

24.13 Mixed Connective Tissue Disease and Overlap Syndromes

G Narsimulu, Vara Prasad IR

DEFINITION

Mixed connective tissue disease (MCTD) is a disease characterised by combination of clinical features of systemic lupus erythematosus (SLE), systemic sclerosis, polymyositis (PM), and rheumatoid arthritis (RA). MCTD is considered as a distinct clinical entity because of the presence of very high anti-U1RNP antibody. A few authorities consider MCTD as a subset of SLE or scleroderma.

EPIDEMIOLOGY

The prevalence is four times less than that of SLE indicating an overall prevalence of 10/100,000. The peak onset of the disease is in the second and third decade, but it can occur in children and elderly also. The female to male ratio is 9:1.

IMMUNOPATHOLOGY

U1nRNP is a subunit of spliceosomes. Spliceosomes are complex nuclear particles involved in the processing of premessenger RNA into mature spliced RNA. Two subunits of spliceosomes are antigenic targets in autoimmunity. These are:

1. Small nuclear ribonucleoprotein particles (snRNPs).
2. Heterogenous nuclear RNP (hnRNP).

The snRNP contains small RNAs that are complexed with proteins. These RNAs contain a high content of uridine and are, therefore, called U RNAs. Five different types of URNAs are defined on the basis of immunoprecipitation (U1, U2, U4, U5, and U6). Autoantibodies to these complexes are mainly directed to the protein components. Antibodies directed exclusively against U1 subunit are known as antiU1RNP antibodies. They precipitate three proteins with molecular weight of 68000, 33000, and 22000. The clinical correlates of MCTD appear to be most closely associated with antibodies to the 68 kD and the 33000 proteins of the U1 RNP complex. A proposed model of RNP self antigen-driven autoimmunity is shown in **Figure 1**.

The characteristic lesions in the involved organs are intensive obliterative proliferative vascular lesions in large, medium and small vessels with less inflammatory infiltrates. There is increased synthesis of type III collagen leading to abnormal type I to type III ratio, unlike scleroderma where the ratio is maintained.

CLINICAL FEATURES

The various features of the connective tissue disorders making up MCTD develop over many months or years. The presenting symptoms are Raynaud's phenomenon, puffy hands, arthralgia, myalgia and fatigue. The fingers as well as the entire hand may become puffy.

SKIN AND MUCOUS MEMBRANE

Skin manifestations include Raynaud's phenomenon, sclerodactyly, skin tightening, photosensitivity, malar rash, and the rash of dermatomyositis and panniculitis. Sclerodermal changes are usually limited to the distal extremities and sometimes the face but spare the trunk. Telangiectasia and calcinosis may also occur. Other lesions include oral uclerations, sicca symptoms, orogenital ulceration, livedo vasculitis, and nasal septal perforation.

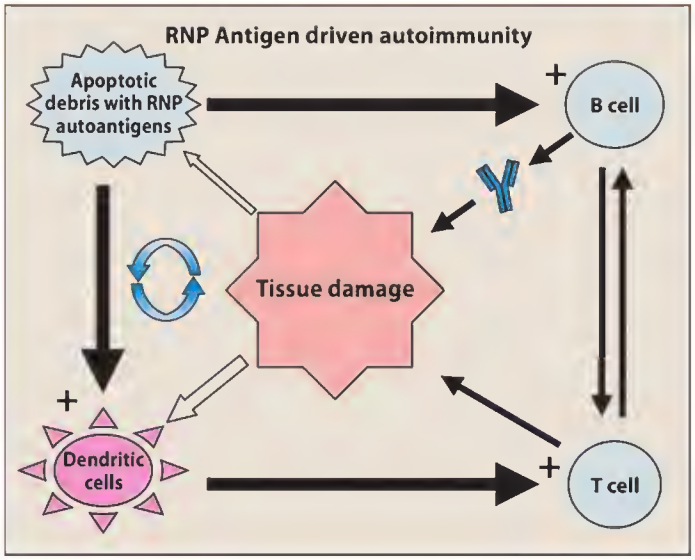

Figure 1: Model of RNP self antigen-driven autoimmunity. Self antigen (including 68kD and U1-RNP) triggers both the innate and adaptive arms of the immune system and breaks immunologic tolerance. Activation of B cells and dendritic cells leads to autoantibody production and also activate T cells leading to tissue damage.

Joints

Joint pains, stiffness and non-erosive peripheral arthritis are common. Joint involvement in MCTD is more common and more severe than seen in SLE. Deformities can occur but joint erosions are uncommon.

Muscle

Myalgia is a common symptom. Myositis also occurs frequently, but most often without significant demonstrable weakness, electromyographic changes or muscle enzyme elevation. Sometimes, it may present as inflammatory myositis with anti-U1RNP antibody without other features of MCTD.

Lung

About 85% of patients have pulmonary involvement, which is often asymptomatic. Low diffusion capacity for carbon monoxide may be the only abnormality. Pleurisy commonly occurs, but is seldom associated with large pleural effusion. Interstitial lung disease (ILD) also is well described in MCTD. HRCT is a sensitive tool to determine the presence of ILD in MCTD. Pulmonary hypertension is the most common cause of death in MCTD. Pulmonary arterial hypertension (PAH) is usually caused by a bland intimal proliferation and medial hypertrophy of pulmonary arterioles. PAH may also be due to coexistent antiphospholipid (APL) antibodies.

Heart

All three layers of heart can be involved in MCTD. Pericarditis may occur in 10% to 30% of cases. Myocardial involvement also is described. ECG changes are seen in 20% cases. Arrhythmias, conduction disturbances and mitral valve prolapse also can occur.

Gastrointestinal System

Gastrointestinal involvement is seen in about 70% patients. The most common manifestations are oesophageal dysmotility, lower oesophageal sphincter laxity, and gastro-oesophageal reflux. Abdominal pain, malabsorption syndrome, and chronic active hepatitis also are described. Pseudodiverticula along the antimesenteric border of colon can occur like in scleroderma.

Kidney

Approximately 25% of patients develop renal disease. Membranous glomerulonephritis is the most common. It is usually mild, but can cause nephrotic syndrome. Diffuse proliferative glomerulonephritis (DPGN) is unusual in MCTD. This is believed to be due to the protective role played by the high titers of anti-U1RNP. Renal crisis secondary to malignant renovascular hypertension is seen in a few patients.

Central Nervous System

Central nervous system (CNS) involvement is rare in MCTD. Trigeminal neuropathy is the most common problem encountered. Vascular headache, aseptic meningitis, peripheral neuropathy, transverse myelitis and sensorineural hearing loss also are described.

Fever

Fever may be prominent feature, can present as pyrexia of unknown origin. Fever may be traced to co-existent myositis, aseptic meningitis, serositis, lymphadenopathy or intercurrent infection.

Haematology

Anaemia of chronic inflammation is seen in 75% of patients. Other abnormalities noted are positive Coombs' test, leucopaenia, thrombocytopaenia, thrombotic thrombocytopaenic purpura and red cell aplasia.

LABORATORY FINDINGS

The diagnosis of MCTD depends on the demonstration of antiU1RNP antibody in high titres. Antinuclear antibody positivity is seen in 100% of patients in high titre with coarse speckled pattern. This finding should prompt the measurement of antibodies to U1RNP, Sm, Ro and La. Anti U1RNP antibodies by haemagglutination test titre > 1:1600 is characteristic feature of MCTD. The absence of anti-Sm antibodies and anti-DNA antibodies in a patient seropositive for anti U1RNP is an important finding discriminating MCTD from SLE.

Other investigations show features common to connective tissue diseases in general. The most frequent haematological findings are leucopaenia, thrombocytopaenia and a high ESR. Serum immunoglobulins may be extremely high, with IgG concentrations reaching more than 40 g/l in some patients. In contrast to SLE, in MCTD the complement concentrations are usually normal or high. Rheumatoid factors are increased in approximately 70% of patients.

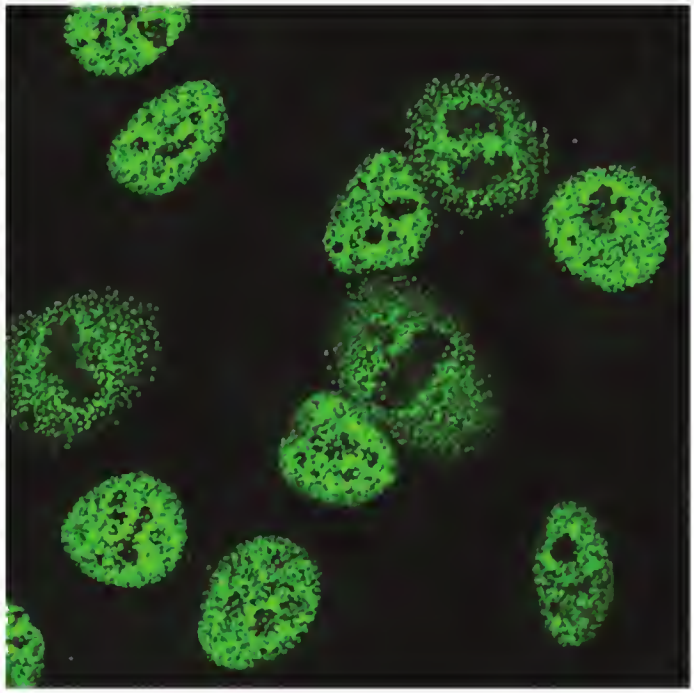

Figure 2: Indirect immunofluorescence on Hep-2 cells with a patient's serum containing anti-U1-RNP antibody. This shows speckled nuclear staining, with characteristic sparing of the nucleoli and negative staining of the chromosomes of the cell in early metaphase.

DIAGNOSIS

The diagnosis of MCTD is clinicoserologic. The two diagnostic criteria for MCTD that are widely employed are Alarcon-Segovia's Criteria and Kahn's Criteria.

Alarcon-Segovia's Criteria

(a) Serologic criteria: High titre anti RNP

(b) Clinical Criteria: Swollen hands, synovitis, myositis, raynaud's phenomenon, acrosclerosis

MCTD present if criteria A accompanied by 3 or more clinical criteria, one of which should be synovitis/myositis.

Kahn's Criteria

(a) Serologic criteria: High titre antiRNP >1:1600 with speckled ANA

(b) Clinical criteria: Swollen fingers, Synovitis, Myositis, Raynaud's phenomenon

MCTD present if criteria A is accompanied by Raynaud's phenomenon and two or more of the three remaining clinical criteria.

When myalagia replaces myositis in diagnostic criteria sensitivity increased to 81.3% from 62.5% with no change in specificity.

PROGNOSIS

The course of MCTD is unpredictable. In most of the patients it has a benign course. It is the major organ involvement that dictates the morbidity and mortality in an individual case.

MANAGEMENT

There is no specific treatment for MCTD. The treatment depends on the pattern of clinical involvement (**Table 1**).

Pulmonary hypertension being the most common cause of death, patients should be evaluated at regular intervals for its development. It should be suspected in patients with increasing breathlessness. Echocardiogram is the most useful screening test. A definitive diagnosis requires cardiac catheterisation showing a mean resting pulmonary arterial pressure more than 25 mmHg at rest.

Table 1: Guidelines for Managing MCTD

Problem	Treatment
Raynaud's phenomenon	Use gloves, keep warm, prevent finger trauma, stop smoking, avoid beta blockers
	Drugs: Nifedipine, Prazosin, bosentan
Arthralgia/Arthritis	NSAID's, hydroxychloroquine, methotrexate
Myositis	Acute severe: high dose Prednisone 60 to 100 mg/day
	Chronic, low grade: low dose Prednisone 10 to 30 mg/day methotrexate or IVIG
Pleurisy/Pericarditis	NSAIDs, low dose Prednisone 10 to 30 mg/day
Myocarditis	Steroids + monthly cyclophosphamide, avoiddigoxin
Nephrotic syndrome	Steroids + monthly IV cyclophosphamide/ daily/oral cyclophosphamide + ACE inhibitors + low dose aspirin and Dipyridamole to prevent thrombotic complications
Aseptic meningitis	High dose steroids
Dysphagia	Proton pump inhibitors and prokinetic drugs (mosapride, domperidone)
Digital gangrene	Anticoagulation, local chemical sympathectomy, endothelin receptor antagonist therapy

Analgesics and nonsteroidal anti-inflammatory drugs alone may be needed in one-third cases. Manifestations like aseptic meningitis, myositis, pleurisy, pericarditis and myocarditis usually respond to corticosteroids. Gloves and calcium channel blockers are useful in Raynaud's phenomenon. Arthritis and cutaneous manifestations respond well to antimalarial agents such as hydroxychloroquine. High dose steroids are indicated for the treatment of severe systemic disease such as vasculitis myositis, or interstitial lung disease. IV gammaglobulin or danazol can be tried in patients with steroid-resistant thrombocytopaenia, refractory myositis and haemolytic anaemia. Unless contraindicated, all patients should take supplementary calcium and vitamin D. Immunosuppressive drugs may be useful for induction of remission or for their corticosteroid sparing effects. The commonly used agents are azathioprine, cyclophosphamide and methotrexate.

OVERLAP SYNDROMES

Overlap syndromes occur when patients meet criteria for the diagnosis of more than one connective tissue disease. Raynaud's phenomenon, arthritis, and sclerodactyly are usually found in most of the overlap syndromes. For example, a patient with SLE who develops erosive arthritis in a distribution similar to RA, is labelled an overlap of RA and SLE. Usually one syndrome gradually takes on the features of another. Sometimes, the features of both diseases may occur concurrently. Sjögren's syndrome commonly overlaps with RA, SLE, Systemic sclerosis, PM, primary biliary cirrhosis, etc. MCTD is a serologic subset of overlap syndrome characterised by the presence of antibodies to U1RNP. Other overlap syndromes include SLE with polymyositis in 4% to 16% of cases, SLE with RA (positive rheumatoid factor, nodules and erosive arthritis) known as '*rhupus*'. Scleroderma can be associated with myositis and limited scleroderma with primary biliary cirrhosis (Raynold's Syndrome). The management of overlap syndromes is dictated by individual organ involvement and not by diagnostic labels. For example, the arthritis of SLE, RA or scleroderma is treated in a more or less similar fashion.

24.14 Inflammatory Muscle Diseases

Alakendu Ghosh, Pradyot Sinhamahapatra

INTRODUCTION

The idiopathic inflammatory myopathies (IIM) are a heterogenous group of acquired muscle disorders, presenting with muscle weakness, increased serum muscle enzymes, abnormal myogram and inflammatory changes in muscle histology. The three major entities in IIM are: polymyositis (PM), dermatomyositis (DM) and inclusion-body myositis. In all age groups, DM is the most common and PM is the least common. Inclusion-body myositis is the most common myopathy above the age of 50.

CLASSIFICATION

The classification is summarised in **Table 1**.

Table 1: Classification of Idiopathic Inflammatory Myopathies (IIM)

1. Primary idiopathic polymyositis
2. Primary idiopathic dermatomyositis
3. Polymyositis or dermatomyositis with malignancy
4. Juvenile dermatomyositis (or polymyositis)
5. Polymyositis or dermatomyositis associated with other connective tissue diseases
6. Inclusion body myositis
7. Rare forms of idiopathic myositis: Granulomatous myositis, eosinophilic myositis, focal myositis, orbital myositis, etc.

CLINICAL MANIFESTATIONS

PM is a subacute myopathy that evolves over weeks to months and presents with proximal muscle weakness. It affects adults, but rarely also children.

The patient presents with painless weakness of the proximal muscles of limbs, trunk and neck flexors over few months (55%), and sometime acute or subacute painful proximal weakness (30%). There may be some constitutional features. Uncommonly, the patient may present with a more indolent course over years, myalgia alone, or a rash alone in DM. Facial and bulbar weakness are rare and ocular weakness is not a feature of idiopathic PM. However, dysphagia due to oropharyngeal weakness occurs in one-third, and signifies poor prognosis.

DM is associated with characteristic cutaneous rash that accompanies muscle weakness (**Figure 1**). These skin manifestations include: (i) typical 'heliotrope' rash, which is a violaceous discolouration around the eyelids, may be oedematous, accompanied by an erythematous rash on the face (ii) Gottron's papules, which are erythematous scaly lesions on the hands, over bony prominences like the knuckles at the metacarpophalangeal and interphalangeal joints; (iii) the erythematous rash on the face, neck, and anterior chest (in many patients in a 'V' sign) or back and shoulders (Shawl sign), lateral

Figure 1: Dermatomyositis with skin rash.

thighs (Holster' sign); and (iv) dilated capillary loops at the base of the finger nails. DM affects both children and adults and women more than men. Juvenile DM may present with calcification. Calcinosis is associated with increased morbidity (**Figure 2**).

Inclusion body myositis (IBM) occurs over the age of 50 years and is more common in men. It usually affects proximal as well as distal muscles and can be asymmetric. Muscle atrophy and swallowing difficulty are prominent in IBM.

Facial and extraocular muscles are never affected. Neck extensor muscles may be involved causing head drop. Myalgia is uncommon occurring in 30% of patients.

IIM may be associated with a number of extramuscular clinical manifestations like fatigue, malaise, weight loss and low-grade fever. Pulmonary involvement in IIM is due to weakness of the thoracic muscles or interstitial lung disease (ILD) (around 40%) or aspiration pneumonia due to pharyngeal weakness. Cardiac involvement in IIM may include atrioventricular conduction disturbances and myocarditis/pericarditis. Joint contractures occur mostly in dermatomyositis. The patients can have dysphagia, or reflux. Gastrointestinal ulcerations due to vasculitis and infection are common in children with dermatomyositis.

Inflammatory myopathies can have association with malignancies in some organs like ovaries, gastrointestinal tract, nasopharyngeal, lung, breast, non-Hodgkin's lymphoma (NHL) specially in elderly people. The malignancy may be during antecedent, or subsequent to myositis onset.

Figure 2: Juvenile dermatomyositis (JDM) with calcinosis.

DIAGNOSIS

The clinical diagnosis of PM and DM is confirmed by three laboratory investigations: (i) serum muscle enzyme concentration, (ii) typical electromyography, and (iii) muscle biopsy histology. In addition, magnetic resonance imaging (MRI), MR spectroscopy can help localisation of extent and autoantibody testing helps in the evaluation.

Autoantibodies like antisynthetase or anti-SRP (signal recognition particles) are found in 20% of patients. Jo-1 antibodies predicted the persistent use of drugs. Antinuclear antibodies (ANA) may be positive in 50% to 80% and rheumatoid factor in 20% of patients (**Table 2**).

Age appropriate screening for malignancy (thorough clinical examination, colonoscopy, mammography, chest computed tomography (CT), abdominal with pelvic CT, stool occult blood, prostate specfic antigens (PSA), serum CA125, CA19-9) is recommended, especially in elderly patients with dermatomyositis, high erythrocyte sedimentation rate (ESR), and/or in presence of cutaneous necrosis on the trunk, cutaneous leucocytoclastic vasculitis, evidence of capillary damage in muscle biopsy.

The most sensitive muscle enzyme assay is creatinine kinase (CK), which is increased up to 50 times the normal upper limit in active disease. CK increases before clinical weakness and falls before clinical improvement. However, CK can be normal in some patients with active DM and late stages of polymyositis. CK levels are normal in corticosteroid induced myopathy. CK may be increased in a number of conditions (**Table 3**).

PM/DM may be associated with other connective disease usually termed as overlap syndrome. DM develops in up to 12% of patients with systemic sclerosis, PM in 5% to 8% of lupus patients.

Table 2: Clinical Profiles of IIM Based on Autoantibodies

Myositis specific antibodies		**Clinical features**
1.	Antisynthetase	PM/DM features, with acute onset muscle weakness; associated with fever, Raynaud's phenomenon, 'mechanic's' hand, interstitial lung disease (Antisynthetase syndrome) (Jo-1 with mainly PM features and other antibodies with mainly DM features)
2.	Anti-signal recognition particle (SRP)	PM features, with very acute onset and severe muscle weakness; cardiac involvement; poor response to treatment; high mortality
3.	Anti-Mi 2	DM features, with acute onset; associated with 'V' sign and 'shawl' design, cuticular overgrowth at fingers; good response to treatment
4.	Anti-MAS	PM features; acute onset; association with alcoholic rhabdomyolysis; good response to treatment
Myositis associated antibodies		**Clinical features**
5.	Anti-Ku and anti-PM-Scl	Associated with a PM and scleroderma overlap clinical picture
6.	Anti-KJ	Associated with PM features, Raynaud's phenomenon and interstitial lung disease
7.	Anti-U1-RNP	Associated with PM/DM overlap syndrome
8.	Anti-Ro/SSA and anti-La/SSB	Associated with DM/PM features and an overlap clinical situation with SLE or Sjögren's syndrome.

Needle electromyography can be helpful for detecting an active myopathic process, recognising that the process is consistent with IIM and excluding other neuropathies and some myopathies. The most common findings are low amplitude, short duration, polyphasic potentials. However, the

Table 3: Causes of Elevated CK Levels other than IIM

Following strenuous and/ or prolonged exercise:	**Muscle trauma:**	**Muscle diseases (other than IIM):**	**Drugs:**	**Endocrine/ Metabolic:**	**Others:**
An important, but often forgotten cause of an isolated elevation of CK	Injury Following EMG Needle stick Surgery	Infections: Viral, bacterial, protozoal or fungal Idiopathic: associated with other connective tissue disorders Dystrophies Metabolic Myocardial infarction Rhabdomyolysis	Toxic myopathy Causing myositis: D penicillamine Direct elevation by reducing the excretion of CK: barbiturates, morphine, diazepam	Hypothyroid Hypokalaemia Ketoacidosis or hyperosmolar state Renal failure Diabetic nephritic syndrome	CNS disease; cerebral ischaemia, head injury, psychosis, delirium tremens Tumours: gastrointestinal, bronchial Pneumococcal sepsis

characteristic triad is: (a) myopathic potentials, (b) fibrillations, positive sharp waves, increased insertional activity, and (c) complex repetitive discharges. Typical electromyographic features may not be present in 10% of patients.

The muscle biopsy is the gold standard and can provide definitive evidence for diagnosing IIM, but at the same time, most common cause of misdiagnosis due to erroneous interpretations. Biopsy should be performed on the side opposite to the electromyogram (EMG) study to avoid needle artifact. MRI might help localising the extent of muscle involvement. In PM multifocal endomysial CD8+ lymphocytic infiltration in histologically healthy muscle fibre is found. In DM, the inflammation is predominantly perimysial and perivascular infiltration by CD4+ lymphocytes.

Skin biopsy findings are not specific for DM, and are not routinely required, but exclude other skin conditions that can have similar clinical appearances.

Differential Diagnosis

Other causes of proximal muscle pain and weakness must be excluded. These are endocrine (hypothyroidism, hyperthyroidism, osteomalacia, Cushing's syndrome—usually steroid induced, Addison's disease) and metabolic causes (hypokalaemia) plus rare causes like muscle enzyme defects. Infectious myositis (viral- HIV, picornavirus, cytomegalovirus (CMV), Epstein-Barr virus (EBV), rubella, influenza; bacterial- pyomyositis, Lyme, tuberculosis, parasitic- Toxoplasma, Trichinella, etc.) needs exclusion. Drugs like statins, fibrates, zidovudine, penicillamine, colchicine, hydroxychloroquine, cyclosporine and alcohol, cocaine are also important causes of muscle pain and weakness.

It is important to note: (i) to exclude PM in suspected muscular dystrophy where the history is short – CK, EMG, and muscle biopsy would help; (ii) to diagnose overlap of PM with another disease like rheumatoid, lupus where assessment of muscle power is difficult because of pain – CK, muscle biopsy helps; (iii) to exclude polymyalgia rheumatica in cases with significant pain, especially in elderly with high ESR; (iv) patients with muscle pain and weakness due to endocrine and metabolic myopathies—clinical suspicion is a must. A summary of diagnosis is given in **Table 4**.

Table 4: Summary of Diagnosis of PM/DM

Symmetrical proximal muscle weakness developing over weeks/ months
Elevated serum muscle enzymes: Creatine kinase (CK), aldolase
Abnormal electromyography: Myopathic potentials (short duration, low amplitude, polyphasic), fibrillation, positive sharp waves, insertional activity, complex repetitive discharges
Abnormal muscle biopsy: Multifocal endomysial mononuclear cell infiltration, degeneration and regeneration
Skin manifestations of dermatomyositis: Gottron's papules, Gottron's sign, Heliotrope rash

TREATMENT

Very few controlled trials are available. The goals of therapy are to improve the ability to carry out activities of daily living by increasing muscle strength and control the extramuscular manifestations of IIM. Improvement in muscle strength rather than a reduction of CK levels should be the clinical parameter that denotes response to therapy (**Figure 3**).

Prednisolone is the first line drug. The initial dose of prednisolone is 1 to 2 mg/kg/d (60-100 mg/day) for 4 to 8 weeks (variable) and then tapered gradually as muscle strength

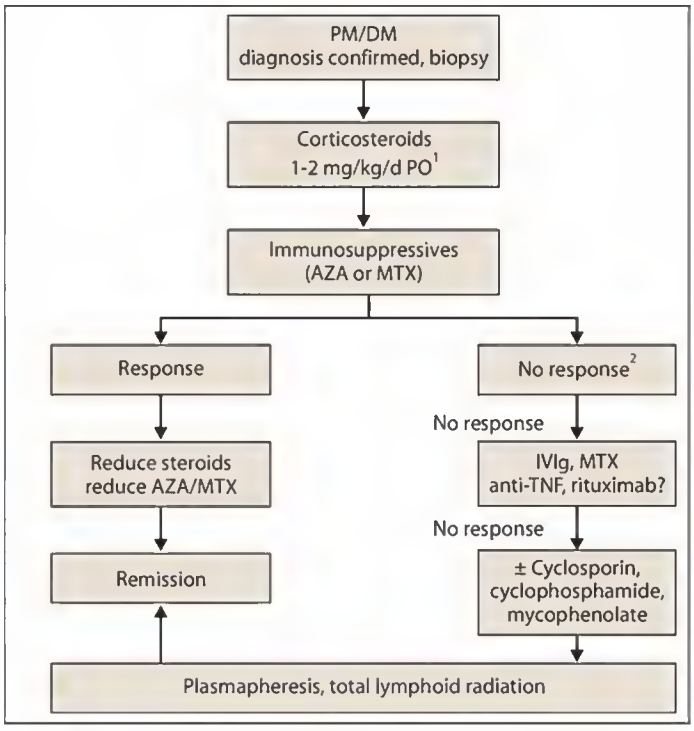

Figure 3: Treatment algorithm for PM/DM.

Notes:
Physical therapy to maintain muscle strength is important at all stages
MTX = Methotrexate; AZA = Azathioprine
1. IV Pulse if ther is alveolitis, dysphagia or myocarditis
2. Is severe disease, IVIg may be added at this stage

improves (reduce dose by 10% every two weeks) over 2 to 3 months, to a maintenance dose of around 0.25 to 0.5 mg/kg per day. Pulsed intravenous methyl prednosolone (15 mg/kg/d, max 1g) is used in severe cases especially with alveolitis, severe dysphagia, or myocarditis. Prevention and monitoring for steroid induced side effects is mandatory. Calcium and bisphosphonate supplementation should be given as necessary.

Most patients will respond to this therapy, but some will require additional immunosuppressive drugs. Increasingly, immunosuppressives are being used along with corticosteroids from begining. Selection of an immu-nosuppressive drug remains empirical and depends on personal experience of treating physician. Azathioprine is given orally in a dose of 2 to 3 mg/kg/day tapered to 1 mg per kg per day once steroid is tapered to 15 mg per day. It can take 4 to 6 months to work. The maintenance dosage is 50 mg per day. Methotrexate is given orally in a dose of 7.5 to 25 mg weekly. This usually acts more rapidly. As dosage increases, taper off steroid dose. Concomitant folic acid minimises side effects of methotrexate. Patients need to be monitored regularly with blood counts, serum creatinine and alanine aminotransferase (ALT). Cyclosporine has also been found to be beneficial and is used in a dose of 3 to 5 mg/kg/day. *Mycophenolate mofetil* is emerging as a promising and well-tolerated drug and is used in a dose of 2 gm/day. Cyclo-phosphamide, given intravenously every 3 to 4 weeks has shown mixed results, but may be of particular benefit for patients with active ILD. Rituximab has been tried in refractory cases. Antimalarials are used for skin lesions in DM. Intravenous immunoglobulin (IVIg) has been shown to be beneficial in improving muscle strength acutely. It is used as a single intravenous infusion of 2 gm/kg. Plasmapheresis was not found to be helpful in a double blind placebo-controlled study.

Lack of improvement of muscle power may be due to relapse or activity (accompanied by rise in CK) or steroid myopathy (CK normal). Neck flexor strength would be unchanged in patients developing steroid myopathy. Muscle power may not recover fully in all subjects. If other features suggest inactive disease, drugs may be reduced.

COURSE AND PROGNOSIS

Disease related death occurred in at least 10% of patients, 20% remained in remission and were off drugs whereas 80% had polycyclic course. DM infrequently relapses, but usually respond to therapy. PM patients have frequent relapses, but recover with less strength after each bout. Patients with IBM and polymyositis with anti-SRP antibody have the poorest prognosis. Older patients, and those with associated malignancy, delayed treatment, and cardiorespiratory complications have poor survival.

24.15 Rheumatic Manifestations of Systemic Diseases

Debashish Danda

INTRODUCTION

Forty per cent of all human beings suffer from some musculoskeletal symptoms during their life time and one-third have a true musculoskeletal disorder. However, at times musculoskeletal symptoms and signs are manifestations of non-rheumatic systemic diseases. Lack of awareness can lead to erroneous or delayed diagnosis of primary illness. Hereditary, inflammatory, infective, neoplastic, metabolic, nutritional, drug-related and psychogenic diseases can present with rheumatic complaints (**Table 1**). Some of the common systemic conditions with rheumatic manifestations are discussed below.

DIABETES MELLITUS

It can cause rheumatic manifestations as direct, indirect or associated features.

Calcaneal Osteolysis

One of the most common rheumatic symptoms in diabetics is foot pain due to calcaneal osteolysis.

Neuropathic Joint (Charcot Joint)

Unlike syphilis in the past, diabetes is now the most common cause of neuropathic joint, the most damaged and deranged joint, one can imagine. It can affect any weight-bearing joint like knees and ankles, but small joints can also be affected. Clinical clues include significant sensory deficit and pain which is far less than what one might expect from the degree of radiologic damage. Osteomyelitis is an important differential diagnosis.

Rotator Cuff Disease

Restricted abduction of shoulders due to degenerative process causing supraspinatus tendonitis, bicipital tendonitis, and subacromial bursitis is fairly common in diabetics, often loosely termed as 'periarthritis'.

Diffuse Idiopathic Skeletal Hyperostosis (DISH)

Also called as Forestier's disease, it is seen in elderly women with diabetes mellitus with back pain. Radiographs reveal exuberant, bridging osteophytosis in spine which superficially resembles ankylosing spondylitis (AS). However, there is no sacroiliitis in DISH in contrast to AS where sacroiliitis is the characteristic feature. DISH is a degenerative condition. It is not specific for diabetes and may be seen even in absence of diabetes mellitus.

Crystal Arthritis

Both gout and pseudogout are found with higher prevalence in diabetics, when compared to non-diabetics. Gout typically afflicts the big toe while pseudogout usually affects large joints with intermittent inflammatory arthritis, mimicking a septic arthritis but without leaving much residual damage. Radiographs in pseudogout may show chondrocalcinosis at various places: triangular ligament calcification of hands or calcifications of intervertebral space, pubic symphysis or knee joint cartilage. Synovial fluid examination under polarising microscope can clinch the diagnosis. Gouty fluid is likely to show needle-shaped intracellular negatively birefringent crystals of monosodium urate (MSU), whereas calcium pyrophosphate dihydrate (CPPD) crystals of pseudogout are blunt, rhomboid-shaped and positively birefringent.

Septic Arthritis

Diabetes is one of the most common conditions associated with septic arthritis and septic bursitis. Joint aspiration and synovial fluid examination by Gram stain and culture are important. *Staphylococcus aureus* and Gram-negative organisms are the usual causative agents. Septic arthritis requires prolonged and aggressive antibiotic treatment with joint lavage. Delay can lead to joint destruction and contractures.

Diabetic Cheiroarthropathy (Prayer Sign or Namaste Sign)

Myxomatous deposition around small joints of hands, tendons and ligaments leads to this complication causing limited joint mobility (LJM). In one series, LJM was diagnosed in 42.9% of type 1 and 37.3% of type 2 diabetic patients. Abnormally thick skin was detected in 31.4% of type 1 and 33.7% of type 2 diabetic patients. Skin abnormalities were observed mainly in patients with LJM. There was a high prevalence of hand flexor tendon abnormalities (18.6%). Decreased range of shoulder and hip mobility and flexor tendon abnormalities were significantly more common in patients with LJM.

Other Musculoskeletal Features in Diabetes

Complex regional pain syndrome (CRPS) or shoulder-hand syndrome or reflex sympathetic dystrophy is often found in diabetics. Other musculoskeletal features include carpal tunnel syndrome, Dupuytren's contracture, sclerodactyly and scleroderma-like skin changes, tendency for early osteoporosis with tendency to fracture vertebra or neck of femur.

HAEMATOLOGICAL MALIGNANCIES

Haematological malignancies can cause arthropathy by direct infiltration, immune complex-mediated inflammatory arthropathy, haemarthrosis due to low platelets and altered clotting mechanisms, septic arthritis or hyperuricaemia-related gouty type arthritis. They are, therefore, notorious masqueraders leading to delayed diagnosis, especially in children. The clue is pain and tenderness out of proportion to findings in the joints, associated low haemoglobin, low platelets, and at times, abnormal white cell counts (high or low) or morphology. Bone marrow examination can be confirmatory. Metaphyseal radiolucent bars in radiographs are a clue for leukaemic arthropathy. Multiple myeloma (predominantly kappa light chain) and primary amyloidosis (lambda light chain predominant myeloma) can present with features exactly like rheumatoid arthritis including subcutaneous nodules, arthritis and carpal-tunnel syndrome. 'Shoulder pad' sign, macroglossia or lytic lesions on radiographs should arouse suspicion of multiple myeloma.

Table 1: Rheumatic Manifestations of Systemic Diseases

Hereditary diseases with rheumatic manifestations
- Heritable collagen diseases, e.g. benign hypermobile joint syndrome, osteogenesis imperfecta, Ehlers-Danlos syndrome, Marfan's syndrome, pseudoxanthoma elasticum, cutis laxa, Stickler's syndrome, spondyloepiphyseal dysplasia, Alport's syndrome, etc.
- Inborn errors of metabolism, e.g. homocysteinuria, alkaptonuria, Menke's kinky hair syndrome, mucopolysaccharidoses, Fabry's disease
- Storage diseases, e.g. Haemochromatosis, Wilson's disease
- Primary immunodeficiency diseases, e.g. DiGeorge's syndrome, Brutton's agammaglobulinaemia, IgA deficiency, common variable immunodeficiency, hyper IgM syndrome, complement deficiency disorders
- Bone and joint dysplasia, e.g. osteochondrodysplasia, spondyloepiphyseal dysplasia, hypophosphatasia

Inflammatory disorders with rheumatic manifestations*
- RA
- Primary Sjögren's syndrome
- SLE
- Overlap syndromes
- Vasculitic disorders

Infective conditions with rheumatic manifestations
- Viral : Hepatitis B, hepatitis C, HIV, parvovirus, Epstein-Barr virus, cytomegalovirus, rubella, coxsackie, echovirus, O'nyong-nyong, chikungunya and dengue
- Bacterial : Septic arthritis, infective endocarditis, melioidosis, brucellosis, Mycobacterial TB, atypical mycobacteria, leprosy
- Parasitic : Guinea worm arthritis, trichinosis causing myositis, filariasis, schistosomiasis, and amoebiasis causing arthralgia
- Fungal : Sporotrichosis

Neoplastic diseases with rheumatic manifestations
- Haematological : Leukaemias, lymphomas, myelomas
- Solid tumours : Renal cell carcinoma, pancreatic carcinoma
- Metastatic process
- Primary amyloidosis

Metabolic diseases with rheumatic manifestations
- Diabetes mellitus
- Hypothyroidism
- Hyperthyroidism
- Hypoparathyroidism
- Hyperparathyroidism
- Acromegaly
- Cushing's syndrome
- Renal tubular acidosis
- Paget's disease

Nutritional diseases with rheumatic manifestations
- Osteomalacia
- Rickets

Drug or treatment related
- Serum sickness like process following vaccination, drugs
- Drug-induced lupus (INH, phenytoin, D-penicillamine, biological agents like TNF-blockers)
- Drug-induced vasculitis (propylthiouracil and leukotriene inhibitors monteleukast/zafirleukast-induced Churg-Strauss syndrome)
- Hyperuricaemia with drugs (Pyrazinamide)
- Myositis/myopathy (statins, zidovudine, penicillamine, steroid)
- Haemodialysis

Psychogenic diseases with rheumatic manifestations
- Chronic pain syndromes (controversial)

**The diagnosis can often be made without difficulty because joint pains are frequently the presenting feature. Other diseases where musculoskeletal involvement is evident include sarcoidosis, inflammatory bowel disease, coeliac disease and psoriasis.*

The classical triad comprises of bone pain, anaemia and renal failure. Bone marrow examination, electrophoresis for 'M' band and serum immunoglobulin levels confirm the diagnosis. There may be higher levels of the pathogenic isotype of immunoglobulins and suppression of the other isotypes, e.g. in IgA meloma, IgA will be high and IgG, IgM and other isotypes may be low in quantity.

Hairy cell leukaemia can present with polyarteritis nodosa-like vasculitis. Some lymphomas can produce dermatomyositis-like presentations, as paraneoplastic manifestation. Other presentations include erythromelalgia in myeloproliferative diseases presenting as red, swollen, warm, stout, and puffy fingers and toes; and cryoglobulinaemic vasculitis in plasma cell dyscrasias, etc. Rheumatic associations of myelodysplastic syndromes include polyarteritis nodosa type systemic vasculitis and polymyalgia rheumatica.

SOLID MALIGNANCIES

Lung cancers causing hypertrophic osteoarthropathy (triad of clubbing, polyarthritis or polyarthralgia and widening of wrists and ankles), panniculitis in pancreatic carcinoma, dermatomyositis/polymyositis in carcinoma of stomach, ovary and several adenocarcinomas are well known entities. Jaccoud's arthritis is described in lung malignancies while scleroderma-like process

may be seen in adenocarcinomas and carcinoid tumours. Solid tumours and tumours of mesenchymal origin can also give rise to oncogenic osteomalacia presenting as out of proportion bony pain and tenderness. Renal cell carcinoma is another malignancy which causes myriad of rheumatological manifestations including arthritis, vasculitis, etc. due to production of pro-inflammatory cytokines by this tumour. Carcinomatous polyarthritis is a special entity mostly associated with explosive onset, asymmetric, large joint polyarthritis often sparing the upper limbs. This can occur even with haematological malignancies, not necessarily with carcinomas alone.

Rheumatic manifestations suggesting a hidden cancer include rapid onset of an unusual inflammatory arthritis, clubbing or diffuse bone pains in a patient 50 years of age or older, chronic unexplained vasculitis, refractory fasciitis, Raynaud's phenomena unresponsive to vasodilator therapy, rapidly progressive digital gangrene or Lambert-Eaton myasthenic syndrome.

Paraneoplastic rheumatological syndromes may coincide, follow or antedate the diagnosis of cancer, or herald its recurrence. The clinical course generally parallels that of the primary tumour, and treatment of the underlying malignancy often results in regression of the rheumatic disorder. Awareness that cancer can cause certain non-metastatic symptoms is important for early diagnosis and treatment of an occult neoplasm. Management consists of control of the underlying cancer and symptomatic treatment of the rheumatic syndrome with nonsteroidal anti-inflammatory drugs.

CHIKUNGUNYA ARTHRITIS

Chikungunya fever is associated with severe arthralgias, myalgias and skin rash. The fever usually lasts a few days. However, the rheumatic complaints can be crippling. The viral polyarthropathy frequently involves the small joints of the hand, wrist and ankles and may also involve other larger joints such as knees and shoulders. The pain may be severe enough to immobilise the patient and interfere with activities of daily living. Rheumatological manifestations are less severe in children in this infection. The arthralgias can persist for weeks to months. Treatment is mainly symptomatic.

MYCOBACTERIAL INFECTIONS

Tuberculosis (TB) usually presents as chronic inflammatory monoarthritis of large joints. Atypical mycobacteria and at times tuberculosis can present with polyarticular large and small joint disease with significant tenosynovitis, associated bursitis and discharging sinuses, similar to fungal arthropathies.

Mycobacteria-related rheumatic manifestations are often classified into four different categories:

1. Direct musculoskeletal involvement of *M. tuberculosis*, including spondylitis, osteomyelitis, septic arthritis, and tenosynovitis.
2. *M. tuberculosis* infection complicating rheumatologic diseases such as rheumatoid arthritis after therapy with tumour necrosis factor-alpha inhibitors.
3. Anti-mycobacterial drug-induced rheumatologic syndromes such as pyrazinamide and ethambutol-induced hyperuricaemia, quinolone-induced tendinopathy, drug-induced lupus with INH.
4. Reactive immunologic phenomena in mycobacterial infection, such as Poncet's arthritis, erythema nodosum, etc.

Poncet's arthritis is a form of reactive arthritis in tuberculosis. It is a sterile arthritis of large or small joints, usually short lasting and non-deforming, thought to be due to hypersensitivity to mycobacterial antigens. It was originally seen after intravesical instillation of BCG vaccine for bladder malignancies. It is more common with extrapulmonary TB, rather than in pulmonary TB. Usually, symptomatic treatment with NSAIDs suffices most of the time. Erythema nodosum seen in the setting of TB can be confused with sarcoidosis. Mantoux test in such a case may be helpful.

LEPROSY AND LEPRA REACTION

Striking rheumatological manifestations can be seen in leprosy and lepra reactions. Type 2 lepra reaction is a type 3 immune response, i.e. immune complex- mediated process similar to SLE. Therefore, it is not surprising to find lupus-like presentations in these patients. They may even present with dermatomyositis, overlap connective tissue disease and medium vessel vasculitis-polyarteritis nodosa-like process. Infiltration of ear lobule and infiltrated appearance of face, depressed bridge of nose, nerve thickening and madarosis can be the clues in a suspected case. In a case of mononeuritis multiplex presenting as foot drop, wrist drop, cranial nerve palsy, one must suspect leprosy if diabetes is ruled out. The other differential diagnosis includes classic polyarteritis nodosa. Seven quadrant slit-skin smear is a good test; the other test is nerve biopsy with appropriate acid-fast staining for *M. leprae*.

HIV

Table 2 shows rheumatic manifestations of HIV. A host of autoantibodies are also described in HIV infection namely: anticardiolipin, anti-beta-2 GPI, anti-DNA, anti-small nuclear ribonucleoproteins (snRNP), anti-thyroglobulin, anti-thyroid peroxidase, anti-myosin and anti-erythropoietin antibodies. The clinical correlation of autoantibodies in HIV-infected patients with clinical autoimmune disease is yet to be established. With the upsurge of HAART (highly active anti-retroviral treatment), the incidence of autoimmune diseases in HIV-infected patients is increasing, especially after immune reconstitution syndrome.

Table 2: Rheumatic Manifestations of HIV

Increased incidence of reactive arthritis due to possible several gastrointestinal infections
Aggressive psoriatic arthritis
Sjögren's-like disease called diffuse interstitial lymphocytosis syndrome (DILS)*
Septic arthritis
Pyomyositis and polymyositis
Systemic lupus erythematosus
Anti-phospholipid syndrome
Vasculitis

**Presents as prominent parotid and lacrimal gland enlargements. This differs from Sjögren's by the presence of CD8-positive lymphocytes infiltration rather than CD4 cells seen in Sjögren's syndrome.*

24.16 Miscellaneous Rheumatic Disorders

Binoy J Paul

This chapter deals with a group of unrelated disorders like heritable connective tissue disorders, relapsing polychondritis, Charcot's arthropathy, hypertrophic osteoarthropathy and pigmented villonodular synovitis.

HERITABLE CONNECTIVE TISSUE DISORDERS

Heritable diseases of connective tissues are a diverse group of disorders characterised by abnormalities in the musculoskeletal tissues including cartilage, bone, tendon, ligament, muscles and skin. They are further classified into disorders primarily affecting the cartilage and bone (skeletal dysplasias) and diffuse disorders that have a more profound effect on the connective tissues like Ehler-Danlos syndrome (EDS), Marfan's syndrome and other disorders manifested by abnormal extracellular matrix molecules.

Skeletal Dysplasias (Osteochondrodysplasias)

These are a group of developmental disorders of the chondral and osseous tissues that are often accompanied by short stature. They include defects of tubular and flat bones or of the axial skeleton, disorganised development of cartilaginous and fibrous component and idiopathic osteolysis.

The most important varieties of skeletal dysplasias are osteogenesis imperfecta, chondrodystrophies like achondroplasia and spondyloepiphyseal dysplasias (**Table 1**).

Table 1: Heritable Diseases of Connective Tissues

Skeletal dysplasias
- Osteogenesis imperfecta
- Chondrodystrophies, e.g. Achondroplasia
- Spondyloepiphyseal dysplasias
- Kniest dysplasia
- Morquio's disease
- Hereditary multiple exostoses
- Diastrophic dysplasia
- Idiopathic osteolysis

Diffuse heritable diseases
- Ehler-Danlos syndrome
- Marfan's syndrome
- Pseudoxanthoma elasticum
- William's syndrome
- Benign joint hypermobility syndrome

Osteogenesis imperfecta (OI)

It is a genetic syndrome of abnormal bone matrix with secondary osteoporosis. OI is one of the most common heritable disorder of connective tissue. It is inherited as autosomal recessive or autosomal dominant manner depending on the disease subtype. It is associated with abnormalities of structure or synthesis of Type I collagen (**Table 2**).

The severity of the disease ranges from a slight increase in susceptibility to bone fractures to forms that are lethal *in utero*. In addition to fracture susceptibility there is marked osteoporosis secondary to osseous matrix abnormality. The skeletal abnormalities varies with the type (**Table 2**).

OI is associated with variable non-osseous features like blue sclera, dentinogenesis imperfecta, deafness, pectoral deformities, mitral valve prolapse and growth retardation. The diagnosis of OI can be usually made clearly on clinical and radiological basis.

Treatment with bisphosphonates or calcitonin may be beneficial to prevent vertebral compression than long bone fractures and to delay the development of scoliosis. These drugs also reduce the bone pain. Long-term management requires expert physical therapy or orthopaedic surgery.

Table 2: Classification of Osteogenesis Imperfecta

Type	Inheritance	Sclera	Deafness	Skeletal abnormalities
I	Autosomal dominant	Blue	50%	Mild to moderate bone fragility No deformities Mild to moderate short stature
II	Autosomal dominant or recessive	Blue	No	Extreme fragility of connective tissue Congenital fractures Soft large cranium Micromelia, Beaded ribs Lethal in the perinatal period
III	Autosomal dominant or recessive	Variable	Common	Progressive deformity of bone Very short stature Relative microcephaly Triangular facies Dentinogenesis imperfecta
IV	Autosomal dominant	Normal	Uncommon	Variable short stature Mild to moderate bone deformities Dentinogenesis imperfecta Moderate joint hyperextensibility

Chondrodystrophies

Chondrodystrophies are a large and strikingly heterogenous group of heritable skeletal dysplasias with abnormal proportion of limbs, trunk and/or skull and often associated with short stature.

Some chondrodystrophies are associated with an abnormality of Type II collagen. However, in most chondrodystrophies the abnormality of extracellular matrix is unknown.

Achondroplasia

Achondroplasia is the most common skeletal dysplasia, which is due to mutation in the gene expressing the fibroblast growth factor receptor 3 (FGFR3). The distinguishing features are present at birth, although the diagnosis is seldom made at that time. The head is large with frontal bossing, midface hypoplasia and prognathism. There is rhizomelic shortening of arms and legs, increased lumbar lordosis, bowing of the legs, overgrowth of fibula and a trident shaped hand with short broad phalanges.

Radiographs show a very small sacrosciatic notch of pelvis, changes in the epiphysis of distal femur and constriction at the base of the skull. Adult life may be shortened if there is spinal canal stenosis causing spinal cord compression. Otherwise most of these persons live a healthy productive and independent life. Limb lengthening involving bilateral femoral and tibial distraction osteotomies may add up to 12 inches to the adult height. The procedures are best done in the second decade.

Spondyloepiphyseal dysplasias

Spondyloepiphyseal dysplasias (SEDs) constitute a group of closely related disorders characterised by short stature and a disproportionately short trunk. Infants with the most severe forms of SEDs are obviously dwarfed at birth. Many other less severely affected patients may not present until later in life and their symptoms can be easily confused with those of osteoarthritis. They present with short stature and symmetric joint pain caused by epiphyseal changes. There are two types of spondyloepiphyseal dysplasias Congenita and Tarda (**Table 3**). Radiographic features include flattening and/or sclerosis of epiphyses of long bones. There will be flattening of the vertebral bodies also.

Table 3: Spondyloepiphyseal Dysplasias

Type	Onset	Inheritance	Associated features
Congenita	Birth	Autosomal Dominant	Short limbs Equino varus feet Myopia, retinal detachment
Tarda	Late childhood	X-linked recessive	Moderately short stature Platyspondyly Onset of pain in the hip and back at the age of about 10 yrs Progressive joint deformities

DIFFUSE HERITABLE CONNECTIVE TISSUE DISORDERS

Ehler-Danlos Syndrome (EDS)

EDS is a genetic syndrome affecting primarily joints, skin and blood vessel all. It consists of a heterogenous group of generalised connective tissue disorders associated with multiple modes of inheritance and associated with abnormalities of types I, III, V collagen or fibronectin, enzyme deficiencies or abnormalities of copper metabolism.

There are around 10 types of EDS. The genetic inheritance and incidence varies with the type.

1. Type 1 EDS is the gravis form. Patients have velvety and hyperextensible skin, marked joint extensibility, cigarette paper scars and easy bruising.
2. Type II EDS (mitis) has a less severe presentation of type I with associated premature degenerative arthritis.
3. In Type III EDS joints are hypermobile with repeated joint dislocations and degenerative arthritis.
4. Type IV (Vascular EDS) is the severest form associated with lethal complications like rupture of arterial wall, colon or pregnant uterus. There is a characteristic facies with large eyes and thin nose and lips. Patients have marked bruisability, an aged skin appearance on hands and feet and joint hypermobility limited to the small joints of hands. Type I to IV are having autosomal dominant inheritance.
5. Type V EDS is clinicaly similar to Type II but the mode of inheritance is X-linked.
6. Type VI EDS is having autosomal recessive inheritance with soft extensible skin, scoliosis, ocular fragility and hypermobile joints.
7. Type VII EDS presents predominantly with joint symptoms beginning with congenital dislocation of hips usually bilateral and continuing with striking joint laxity and multiple dislocations. There may be moderate short stature and mild skin bruising and extensibility.
8. Type VIII EDS is associated with generalised periodontitis in addition to skin and joint hyperlaxity.
9. Type IX EDS has bladder diverticula and rupture, soft lax skin associated with bony occipital horns.
10. Type X EDS is associated with abnormal platelet aggregation in addition to mild joint hypermobility and easy bruising.

Management of EDS is mainly conservative. Joint hypermobility generally decreases with age. Sports that hyperextend and otherwise stress the joints should be discouraged in childhood. Joint surgery may be performed for pain, instability or poor range of motion. Skin fragility in EDS necessitates particular attention to closure in even minor surgical procedures. Sutures should be more closely spaced and left in place for a longer period than normal. In Type IV EDS, patient should be asked to report to the physician for all appropriate vascular and visceral symptoms for prompt evaluation. If pregnancy is attempted, elective caesarean section through lower uterine segment is essential to prevent uterine rupture or vaginal tears.

Marfan's Syndrome (MS)

Marfan's syndrome was the first heritable connective tissue disorder to be described which has an autosomal dominant inheritance. There is no racial or geographic influence on incidence with an approximate prevalence of one per 20,000.

Aetiopathogenesis

Classic Marfan's syndrome is caused by mutation in fibrillin-1 (FBN-1) gene. Fibrillin is a glycoprotein abundant in aortic tunica media, ciliary zonules, skin and periosteum.

Clinical features

Musculoskeletal features include stature greater than 95 percentile and limbs disproportionately long for trunk size (arachnodactyly), scoliosis, pectus excavatum or carinatum, high arched palate, flat feet and marked laxity of joints. Ocular features include non progressive upward subluxation of lens and myopia. Cardiovascular manifestations include mitral valve prolapse and dilatation of ascending aorta which lead to mitral or aortic regurgitation. Ghent nosology (Table 4) helps in the diagnosis of Marfan's syndrome.

Table 4: Ghent Nosology of Marfan's Syndrome

Skeletal system (four or more of)	Ocular system
Pectus carinatum	Ocular system
Pectus excavatum	Ectopia lentis
Span to height >1.05	Cardiovascular
Wrist and thumb sign	Dilatation of ascending aorta involving at least sinuses of Valsalva
Scoliosis >20°	
Elbow extension <170°	Dissection of aorta
Pes planus	Family/Genetic history
Protrusio acetabulae	First degree relative with Marfan's syndrome
Lumbosacral dural ectasia by CT/MRI	Presence of FBN-1 mutation

For index case: Diagnosis requires major criterio in at least two different organ systems and involvement of a third organ.

For a relative of index case: Major criterion in one organ system and involvement of a second organ system.

Management

Management of Marfan's syndrome is multidisciplinary including periodic ophthalmology, orthopaedics, cardiovascular and rheumatology evaluation. Surgical intervention may be needed when scoliosis exceeds 45°. Cardiovascular care includes periodic ECG and echocardiographic evaluation for aortic root dilatation. Treatment with β-blockers decreases the rate of aortic root dilation and increases survival. Aortic surgeries for aneurysms, valve regurgitation using composite graft to replace both ascending aorta and aortic valve has markedly increased the survival in these patients. Pregnancy is better avoided in women with Marfan's syndrome having moderate aortic dilatation.

Benign Joint Hypermobility Syndrome

Benign joint hypermobility syndrome (BJHS) is a common disorder which is strongly heritable. It is characterised by the development of symptoms in otherwise healthy individuals with hypermobile joints. Some of the workers regard it as being the same as Ehler-Danlos syndrome Type III (EDS-Hypermobility type). It is three times more common in females and exhibits a dominant inheritance with variable penetrance.

Clinical features

Trivial strain or injury to the joints, ligaments, tendons or enthesis can cause pain, swelling in these patients. Recurrent joint instability or subluxation could be the initial symptoms in some patients. Secondary osteoarthritic/spondylotic changes in the peripheral or spinal joints can occur later in life.

Extra-articular features include soft silky skin, hiatus hernia, rectal prolapse, uterine prolapse and varicose veins which can occur in some of these patients. Mitral valve prolapse and spontaneous pneumothorax are rare manifestations. BJHS patients also display Marfanoid habitus increased skin stretchiness and other manifestations overlapping with other heritable diffuse connective tissue diseases. Brighton's criteria will help to make a diagnosis of hypermobility syndrome (Tables 5 and 6).

Table 5: Brighton Hypermobility Score – Nine Points

No.	The ability to	Right	Left
1.	Passively dorsiflex the 5th metacarpophalangeal joint to ≥90°	1	1
2.	Oppose the thumb to volar aspect of the ipsilateral forearm	1	1
3.	Hyperextend the elbow to ≥10°	1	1

Table 6: The 1998 Brighton Revised Diagnostic Criteria for the Benign Joint Hypermobility Syndrome (BJHS)

Major criteria

A Brighton score of 4/9 or greater (either currently or historically)

Arthralgia for longer than 3 months in 4 or more joints

Minor criteria

A Brighton score of 1, 2 or 3 out of 9 (0,1, 2 or 3 if aged 50+)

Arthralgia in one to three joints or back pain or spondylosis; spondylolysis or spondylolisthesis

Dislocation in more than one joint or in one joint on more than one occasion

Three or more soft tissue lesions

Marfanoid habitus

Skin striae, hyperextensibility, thin skin or abnormal scarring

Eye signs, drooping eye lids, myopia or antimongoloid slant

Varicose vein, hernia, uterine/rectal prolapse

BJHS is diagnosed in the presence of two major criterio or one major and two minor criterio or four minor criterio. Two minor criterio will suffice if there is an affected 1st degree relative. Major criterio one and two are mutually exclusive.

Management

Simple analgesics or anti-inflammatory drugs are useful in pain and soft tissue injuries. The widespread chronic pain can be treated with serotonergic and noradrenergic agents. Physiotherapeutic approaches include building up of muscles responsible for joint and core stability, avoiding harmful postures and mobilising techniques to restore the normal tensile strength of lax tissues.

Relapsing Polychondritis

Relapsing polychondritis (RP) is a rare autoimmune disease of unknown aetiology with episodic but potentially progressive inflammatory manifestations, primarily involving cartilaginous structures of the ear, nose, eyes, airways and joints. It affects people of 40–60 years age group with equal frequency in both sexes. Over 30% of the cases are associated with an existing autoimmune or haematological disease (Table 7).

Table 7: Conditions Associated with Relapsing Polychondritis

Rheumatoid arthritis
Systemic lupus erythematosus
Scleroderma
Sjörgen's syndrome
Seronegative spondyloarthritis
Wegner's granulomatosis
Polyarteritis nodosa
Churg-Strauss vasculitis
Behçet's disease
Myelodysplastic syndromes
Lymphoma
Inflammatory bowel disease
Primary biliary cirrhosis

Pathogenesis

Autoimmune reaction of unknown aetiology stimulates the release of degenerative enzymes causing cartilage destruction. The cartilage matrix is initially infiltrated with mainly mononuclear and occasionally plasma cells and later leads to fibrosis and calcification.

Clinical features

Auricular chondritis is the key manifestation and is rarely absent in the course of the disease. Acute episodes manifest with pain, tenderness, swelling, warmth and marked redness affecting helix, antihelix or tragus sparing the soft lobule which lacks cartilage. Attacks resolve spontaneously within days but relapses invariably, leading to induration of pinna, drooping or cauliflower ear. Nasal conduits are far less obvious resulting in nasal pain tenderness mild swelling or redness and can cause saddle nose deformity. Laryngeal, tracheal and bronchial conduits can lead to hoarseness of voice, stridor, cough or expiratory dyspnoea. Costal chondritis provokes localised parietal pain and rarely results in depression of anterior chest wall.

Joint manifestations vary from arthralgia to oligo or polyarthritis which can be acute and migratory or chronic non-erosive and non-deforming variety. Peripheral arthropathy is usually asymmetric and mainly affects the wrists, metacarpophalangeal and proximal interphalangeal joints, elbows, knees and ankles.

Vestibular dysfunction, hearing impairment, conjunctivitis, uveitis, keratitis, episcleritis, ascending aortic aneurysm, glomerulonephritis, cutaneous or CNS vasculitis can also occur.

Diagnosis

Although the diagnosis of RP is relatively easy many conditions can mimic the initial changes or the associated disease may confuse the clinical picture. An empirical diagnostic criterion has been evolved (**Table 8**).

Investigations

Elevation of acute phase reactants occur during acute flares, tests for rheumatoid factor or ANA can be positive. Histological examination of the affected cartilage is suggestive of the diagnosis when it shows the association of degenerative changes with the presence of inflammatory cell infiltrates especially CD4+ lymphocytes, macrophages and polymorphonuclear cells. Loss of basophilic staining of the matrix is also seen reflecting the proteoglycan depletion.

Table 8: Diagnostic Criteria for Relapsing Polychondritis

Major Criteria

- Proven inflammatory episode involving auricular cartilage
- Proven inflammatory episode involving nasal cartilage
- Proven inflammatory episode involving laryngo tracheal cartilage

Minor Criteria

- Ocular inflammation (Conjunctivitis, keratitis, episcleritis, uveitis)
- Hearing loss
- Vestibular dysfunction
- Seronegative inflammatory arthritis.

When two major criterio or one mojor and two minor criterio ore present diognosis is confirmed.

Treatment

Systemic treatment is empirical and should depend on the clinical manifestation, disease activity and severity. In mild auricular or nasal chondritis and arthritis nonsteroidal anti-inflammatory drugs (NSAIDS), colchicine, dapsone or low dose prednisolone can be used. Methylprednisolone 'pulses' (1gm/day for 3 days) are useful in frank respiratory flares, recent sensory neural deafness or systemic vasculitis. Immunosuppression with methotrexate (0.3mg/kg/week) or cyclophosphamide (50-150 mg/day) in addition to steroids is used in severe resistant cases. Local steroids (eye drops, intra articular injections or inhaled steroids) are useful in ophthalmic articular or airway diseases. Airway obstruction or stenosis may need tracheostomy or stents.

Neuropathic Arthropathy (Charcot's Joint)

Neuropathic joint disease (Charcot's joint) is a progressive destructive joint disease associated with sensory loss. The common causes are diabetes mellitus, leprosy, tabes dorsalis, syringomyelia, hereditary sensory neuropathies, amyloidosis and spinal cord trauma.

Clinical features

The distribution of the joint involvement depends on the underlying neuropathy as shown in **Table 9**. The onset of neuropathic arthropathy is usually gradual. The joint will be swollen and warm. Because, there is relatively little pain, patient often do not seek medical consultation until progressive deterioration has occurred. Arthralgia is well documented in 50% of patients though the symptoms are usually less than expected from the degree of joint destruction.

Table 9: Joint Involvement in Neuropathic Arthropathy

Disease	Site of involvement
Diabetes mellitus	Metatarsophalangeal, tarsometatarsal, intertarsal joints
Leprosy	Tarsal, tarsometatarsal joints
Syringomyelia	Shoulder, elbow, wrist
Hereditary sensory neuropathy	Knee, ankle, intertarsal Metatarsophalangeal joint
Tabes dorsalis	Knee, hip, ankle
Amyloidosis	Knee, ankle

Investigations

Plain radiography in early stages shows joint effusion periosteal calcification or minimal subluxation. Subsequently

fragmentation of articular surface occurs leading to complete joint disorganisation. This is associated with prominent periosteal new bone formation. Osteocartilaginous bodies of synovial origin and fragments from articular surface lead to a great deal of osseous debris inside the joint. Osteosclerosis and osteophytosis are very prominent radiological features. Synovial fluid may be serous, sero-sanguinous and lipid crystals secondary to subchondral bone lesions may be seen.

Treatment

The management of Charcot's joint consists of joint immobilisation and rest for stabilisation of the joint. Weight bearing may be avoided and orthotic devices like plaster cast crutches stabilising splints or braces are used as required to permit limited mobilisation. The treatment of basic neurological disease usually does not prove beneficent to the joint. Recently bisphosphonates like pamidronate have been used successfully to halt the underlying bone resorption in neuropathic arthropathy.

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy (HOA) is a syndrome characterised by abnormal proliferation of the skin and osseous tissues at the distal part of extremities, clinically manifesting as clubbing, periostosis of tubular bones and synovial effusions. HOA is classified as primary or secondary and the latter having very diverse aetiologies as shown in **Table 10**. There is now evidence to sustain the belief that clubbing and HOA represent different stages of same disease process. In majority of cases the finger deformity is the first manifestation and as the syndrome progresses periostosis becomes evident.

Table 10: Classification of Hypertrophic Osteoarthropathy

Primary (Patchy dermoperiostosis)	
Secondary	
Pulmonary	
	Bronchogenic carcinoma, lung abscess, emphysema, Bronchiectasis
	Pulmonary fibrosis, Mesothelioma of pleura, arteriovenous fistula
Cardiovascular	
	Congenital cyanotic heart disease, bacterial endocarditis, Aortic aneurysm, Eisenmenger's syndrome
Hepatic	
	Cirrhosis, hepatoma
Intestinal	
	Inflammatory bowel diseases, oesopharyngeal or colonic carcinoma
Miscellaneous	
	Graves' disease, thymoma, thalassemia, connective tissue diseases

Clinical features

Primary HOA (Patchy dermoperiostosis) is an autosomal dominant condition characterised by insidious development of clubbing with cylindrical thickening of forearm and legs. Recurrent mildly symptomatic joint effusions may be accompanied. Facial features may be thickened and furrowed with nasolabial fold and a corrugated scalp known as 'Leonine' facies. Skin may show excessive sweating and a 'greasy' feel. Other features include gynaecomastia, acne vulgaris, striae and cranial suture defects.

Investigations

ESR may be elevated with increase in serum alkaline phosphatase (due to considerable new bone formation). Synovial fluid is characteristically non-inflammatory.

Radiological examination shows periosteal new bone formation often seen in the tibia, radius, ulna, fibula and femur. The coarse layered appearance is most evident along the diaphysis. Radionucleotide bone scan and MRI are more sensitive in detecting periosteal reaction earlier than plain radiography.

Treatment

For patients with painful osteoarthropathy, NSAIDs are effective in alleviating pain. Treatment of the underlying disease results in dramatic regression of all features of secondary HOA. Vagal block and vagotomy are also helpful in symptomatic relief.

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis (PVNS) is a benign proliferation of the synovial tissue that usually presents as an indolent progressive monoarthritis or tenosynovitis. The disease usually affects young adults. The synovium has a brownish colour and has numerous large fingers like villi. The proliferated synovium grows into the subsynovial tissue and invades the adjacent cartilage and bone.

Patients often present with insidious onset of pain and swelling of the affected joint, most often the knee rarely hip or ankle. Radiographs show joint space reduction, erosions and subchondral cysts. Joint fluid can be brown or black in colour. Treatment consists of total synovectomy followed by irradiation of the joint.

24.17 Emergencies in Rheumatology

Lata S Bichile, Vaibhav C Chewoolkar

INTRODUCTION

Rheumatological emergencies do occur in a considerable number of patients. The first presentation itself can be an emergency. Presentation may vary depending on the underlying disease process. If the underlying disease is already known, approach towards diagnosis is easier as compared to cases presenting for the first time.

EMERGENCIES IN RHEUMATOID ARTHRITIS (RA)

Septic Arthritis

Septic arthritis is caused by pyogenic bacteria. The infection spreads through the bloodstream, or through surgery, an injection, or injury. The causative organism is usually *Staphylococcus* or *Streptococcus*. In adults, gonococci and mycobacteria may be the causative agent. Intravenous drug users and immunocompromised are more likely to have septic arthritis caused by gram-negative bacteria. Symptoms are, severe pain and swelling in the affected joint (**Figure 1**). Chills and fever are also common. Septic arthritis in the hip may be experienced as pain in the groin area that becomes much worse if the patient tries to walk. Synovial fluid should be tested for TLC, which is usually high, and for bacteria and other organisms. A culture of blood and synovial fluid should also be done and radiographs obtained to assess any joint damage. Antibiotics should be started and should be continued for at least six weeks. Draining the fluid from the infected joints may be required. Surgical drainage is reserved for septic arthritis of the hip, as that site is inaccessible for repeated fluid removal. Splinting can relieve pain. After a period of rest, gentle exercise to prevent stiffness should be started. Recovery is usually good, although many patients will develop osteoarthritis or deformity.

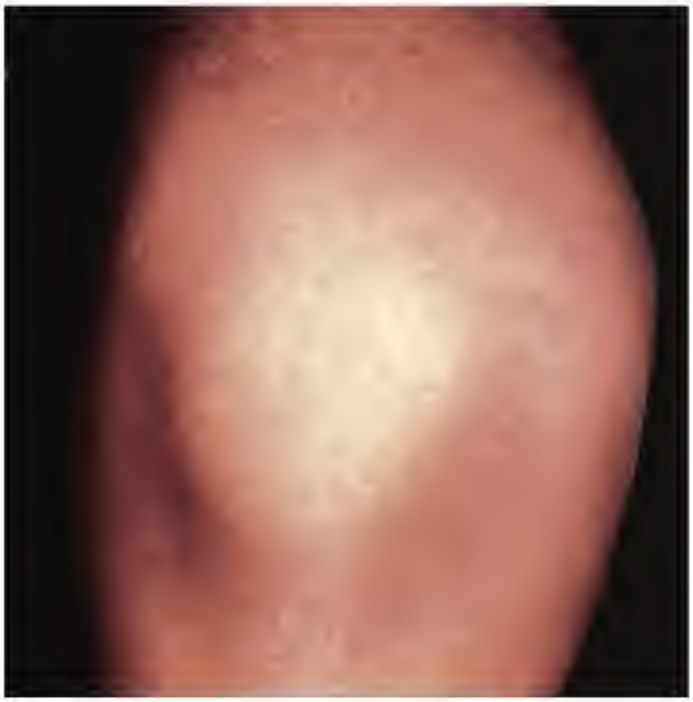

Figure 1: Septic arthritis of the knee joint.

Atlantoaxial Dislocation

Atlantoaxial subluxation is a well-recognised complication of RA. Anterior subluxation is most common, but vertical subluxation of the dens may also occur. Symptoms include paraesthesia, numbness, and muscular weakness. In severe cases this can result in spastic paralysis, paraplegia, tetraplegia, sensory loss and also loss of bladder control, faecal incontinence, and syncope. Physical examination may reveal upper motor-neuron weakness, hyper reflexia, and a positive Babinski's sign. Immediate immobilisation should be done. Magnetic resonance imaging (MRI) is valuable for the assessment of spinal cord damage. A single horizontal or vertical spinal dislocation without significant neurologic features requires no surgical intervention. A neck collar may suffice and, if necessary, non-steroidal anti-inflammatory drugs (NSAIDs) and simple neck traction. Neurologic symptoms and signs of cord compression is a strong indication for neurosurgery. Different surgical techniques are now being developed which allow removal of the odontoid peg and/or fusion without the need for long periods of immobilisation.

Rheumatoid Heart Disease

Pericarditis and rheumatoid valve involvement occurs in seropositive patients with subcutaneous nodules. This usually involves the mitral and aortic valve. Rheumatoid aortic valve disease may be haemodynamically significant and it can be rapidly progressive simulating aortic cusp rupture. Pericarditis occurs in 30% to 50% of patients. Rapidly progressive effusive pericarditis is associated with high morbidity. Pericarditis resolves as the rheumatoid disease is controlled. Symptomatic patients generally respond to NSAIDs. Occasionally, gluco-corticoids are required if the symptoms are severe. Heart failure will require diuretics and inotropic agents. Cardiac tamponade will require therapeutic aspiration. Valve replacement may be indicated in patients with severe or progressive valvular stenosis or regurgitation.

Acute Upper Airway Obstruction

Cricoarytenoid arthritis can occur in RA. Rheumatoid nodules can develop within the larynx and trachea and can erode through local structures. If large, the nodules can cause dyspnoea, due to obstruction of the larynx, especially during acute infections. Symptoms may range from dysphonia to frank aspiration and even acute airway compromise. Indirect laryngoscopy in the acute phase reveals erythema and swelling of the arytenoid mucosa. Operative direct laryngoscopy is the standard for definitive diagnosis of cricoarytenoid joint fixation. High resolution computed tomography (HRCT) is the investigation of choice in assessing cricoarytenoid involvement.

Management consists of tracheostomy for an acute obstruction. Medical treatment includes corticosteroids at the earliest. Periarticular local steroid injections have helped in ameliorating acute joint dysfunction.

EMERGENCIES IN SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Acute Transverse Myelitis

It presents as a rapidly progressive motor, sensory and autonomic dysfunction. The risk increases in the presence of antiphospholipid antibodies (APLA) syndrome. The pathogenesis of acute transverse myelitis may be related to a vascular thrombosis, or to a direct interaction between antiphospholipid antibodies and membrane phospholipids at the spinal cord level. Clinical presentation is with sudden onset of leg weakness or sensory loss and/or bowel or bladder dysfunction. Evolution of the neurodeficit is complete by 1 to 2 days. Thoracic spinal cord is most commonly involved followed by lumbar and cervical.

Cerebrovascular Accident

Vasculitis, local thrombosis or artery-to-artery emboli sometimes manifests with clinical stroke syndromes (**Figure 2**). Emboli can occur as a result of Libman-Sacks endocarditis which produces sterile vegetations on the heart valves. Strokes may be secondary to treatment of SLE, as steroids can cause atherosclerotic changes. Evidence of disease activity in other organs is helpful. Important is to evaluate cerebrospinal fluid (CSF) to rule out infection. CSF abnormalities, such as elevated cell count, elevated protein, or reduced glucose, may be present in one-third of the patients. Low levels of C4 and other complement components have also been detected in the CSF. MRI appears to be superior to conventional computed tomography (CT). Nuclear magnetic resonance (NMR) spectroscopy may provide better demonstration of brain lesions.

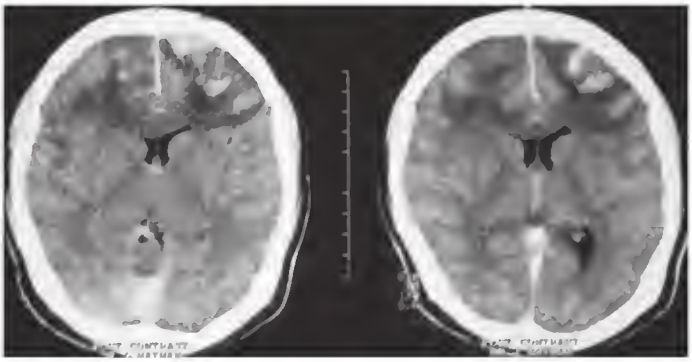

Figure 2: MRI showing venous infarcts in SLE.

Corticosteroids are the most important class of drugs available. Methylprednisolone (0.5 to 1g per day) intravenously for 3 to 5 days followed by oral prednisolone 1 mg/kg should be employed. Intravenous cyclophosphamide (0.5 to 1 g) has also been reported to be effective in serious forms of central nervous system manifestations. With APLA, anticoagulation is necessary. For progressive unresponsive disease, plasmapheresis or intravenous immunoglobulin may be considered. Usual therapies for seizures should also be employed.

EMERGENCIES IN SPONDYLOARTHROPATHIES

Uveitis

Uveitis is the most common extra-articular manifestation in ankylosing spondylitis. The incidence is higher in individuals who are HLA-B27 positive. Uveitis may also be seen in other spondyloarthropathies including reactive arthritis, undifferentiated spondyloarthropathy and psoriatic arthritis. Presentation is usually acute and unilateral, with a painful red eye, photophobia, increased lacrimation, and blurred vision. The involvement is usually anterior, rarely involving posterior elements. The iris is oedematous and discoloured. Pupil may become irregular if posterior synechiae form. There is copious exudate in the anterior chamber of the eye, which can be seen on slit-lamp examination. In most cases topical therapy with corticosteroid eye drops and mydriatics is all that is required. The eye may need to be protected from the light to ensure comfort during the period of pupillary dilatation. Administration of steroids orally, intravenously or by intraocular injection is required when local treatment fails to relieve the inflammation. Inadequate treatment may lead to adhesions and secondary glaucoma.

EMERGENCIES IN VASCULITIDES

Alveolar Haemorrhage and Pulmonary Renal Syndrome (PRS)

Alveolar haemorrhage is a medical emergency and occasionally is the initial presenting manifestation. Pulmonary-renal syndrome is diffuse alveolar haemorrhage and glomerulonephritis occurring simultaneously. Haemoptysis is the most classic finding in combination with peripheral oedema and haematuria or other signs of glomerulonephritis. Bleeding is from low-pressure vessels but it is rarely massive. Haemoglobin levels can drop dramatically. Pulmonary infiltrates may be diffuse or patchy, and usually are perihilar, sparing the apices (**Figure 3**). The renal pathology is small-vessel vasculitis resulting in a form of focal proliferative glomerulonephritis. Goodpasture's syndrome is the prototype cause, but Wegener's granulomatosis, microscopic polyangiitis, and, less commonly, other vasculitides can also cause pulmonary renal syndrome.

Figure 3: X-ray chest of a patient with pulmonary haemorrhage in *Polyarteritis nodosa*.

Initial testing includes urinalysis for evidence of haematuria and red cell casts (suggesting glomerulonephritis). Diffusion

capacity of carbon monoxide (DLCO) may be increased. Bronchoscopy is important to exclude infection and to document the presence of blood when there is no haemoptysis. Hemosiderin-laden macrophages provide proof that bleeding has occurred within the lung. Serum antibody testing may help distinguish some causes, such as antiglomerular basement membrane antibodies in Goodpasture's syndrome, antinuclear antibodies (ANA), and anti-deoxyribonucleic acid antibodies in SLE, anti-neutrophil cytoplasmic antibodies (ANCA) directed against proteinase-3 (PR3-ANCA) in Wegener's granulomatosis, perinuclear ANCA (p-ANCA) in microscopic polyangiitis. Definitive diagnosis requires lung biopsy and/or renal biopsy.

Standard therapy includes pulse intravenous methylprednisolone (500 to 1000 mg once a day for 3 to 5 days). Mechanical ventilation with high positive end expiratory pressure may be required. As life-threatening features subside, the dose can then be reduced to 1 mg/kg, prednisone tapered gradually over the next 12 weeks. Cyclophosphamide should be added at a dose of 0.5 to 1 g/m^2 administered intravenously as a monthly pulse or 1 to 2 mg/kg per day orally. Maintenance therapy includes low-dose corticosteroids coupled with cytotoxic agents.

Visual Impairment in Giant Cell Arteritis (GCA)

Permanent visual loss is one of the most dreaded manifestations of GCA. Visual disturbances have been described in 25% to 50% of cases, although the incidence of visual loss is much lower, about 6% to 10% in most series. Blindness might be partial or complete. Other visual symptoms include transient or permanent diplopia or ptosis. Loss of vision in GCA is caused by inflammation in the arteries supplying the optic nerve head or retina. Involvement of the second eye can occur. On early fundoscopy, the optic disc is pale and swollen whereas the retina appears almost normal. Within 4 to 6 weeks, the optic disc becomes atrophic, with a chalky appearance. The retina will appear greyish, swollen and a contrasting red zone, 'cherry red spot', can be seen in the macula.

Acute phase reactants like erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) are commonly elevated. Often there is normocytic normochromic anaemia. Colour doppler ultrasonography may show a dark 'halo' around the lumen of temporal arteries, stenoses or occlusion may also be found. Temporal artery biopsy, however, remains the gold standard.

Oral steroids are commonly used but intravenous methylprednisolone can be used for severe cases. The treatment is initiated at 1 mg/kg per day of prednisolone for 4 to 6 weeks followed by taper of 5 mg every 1 to 2 weeks while monitoring clinical symptoms and ESR or CRP. Azathioprine has been shown to exert a modest corticosteroid-sparing effect. There has been a value of methotrexate in corticosteroid-resistant cases.

Acute Mesenteric Vasculitis

Abdominal pain caused by bowel ischaemia secondary to mesenteric vasculitis is an uncommon complication of systemic vasculitis. Bowel ischaemia can lead to perforation and haemorrhage, and has a high mortality. The onset may be acute and severe (e.g. mesenteric infarction) or chronic due to mesenteric ischaemia. Chronic mesenteric ischaemia may be manifested by a variety of symptoms including abdominal pain after eating ('intestinal angina'), weight loss, nausea, vomiting and diarrhoea. Ultrasonography demonstrates oedematous bowel loops. Gastroscopy and colonoscopy can show signs of ischaemia and ulceration. Common CT findings include dilated bowel, focal or diffuse bowel-wall thickening, abnormal bowel-wall enhancement, mesenteric oedema, engorgement of mesenteric vessels and ascites. Vascular thromboembolism and aneurysms that involve fairly large vessels can also be demonstrated by conventional or CT angiography (**Figure 4**).

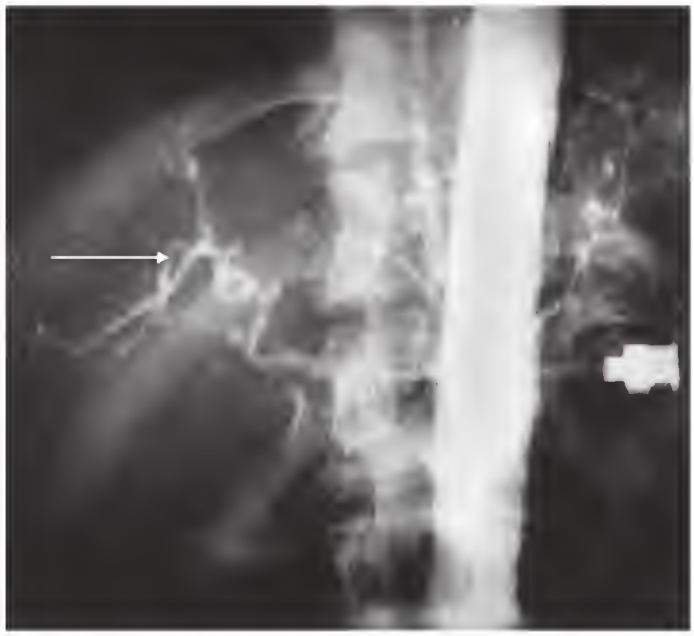

Figure 4: Coeliac angiography with superior mesenteric artery cannulation revealing aneurysm at porta hepatis in a patient with *Polyarteritis nodosa*.

Aggressive anti-inflammatory immunosuppressive treatment should be initiated. The treatment of choice is high-dose intravenous infusions of methylprednisolone or an equivalent agent. Use of heparin is a double edged sword and its use is to be decided on individual basis. In non responding patients and with severe haemodynamic compromise, surgical management is required.

Mononeuritis Multiplex

The onset may be sudden, with pain and paresthesias radiating in the distribution of a peripheral nerve, followed in hours or days by a motor deficit of the same peripheral nerve. This may progress asymmetrically to involve other peripheral nerves and produce a mononeuritis multiplex or a multiple mono-neuropathy. All sensory modalities and motor functions may be affected. Nerve conduction studies should be done at the earliest. Confirmation is by nerve biopsy. Small arteries in the epineurium are affected. Changes include fibrinoid necrosis in acute lesions to intimal proliferation and perivascular fibrosis in more chronic lesions. Methylprednisolone 500 to 1000 mg intravenously for 3 to 5 days should be used to obtain a rapid response followed by oral corticosteroids. Other immunosuppressives like cyclophosphamide, azathioprine, methotrexate, cyclosporine and *Mycophenolate mofetil* can also be used. Plasmapheresis and IVIG are reserved for fulminant cases.

EMERGENCIES IN SYSTEMIC SCLEROSIS

Scleroderma Renal Crisis

Scleroderma renal crisis is characterised by sudden onset of accelerated hypertension, rapidly progressive renal

insufficiency, microangiopathic haemolysis, and consumptive thrombocytopaenia. Markedly elevated plasma renin activity and dramatically rising creatinine is found in most cases. Renal crisis must be considered in any patient with scleroderma whose blood pressure rises even mildly above previous recordings.

Vasospasm occurring on pre-existing renal arteriolar disease is thought to cause excessive renin release. The subsequent effects of angiotensin II induce further renal cortical ischaemia and fixed loss of cortical blood flow and necrosis. Vascular injury in the form of intimal disruption, fibrin deposition and micro-angiopathic haemolysis is the sequel. Corticosteroid therapy has been postulated as an associated factor. Anaemia and thrombocytopaenia occurs, blood smears demonstrating fragmented red cells, followed by increase of fibrin degradation products and reticulocytosis. Urine analysis typically reveals protein and red cells.

Aggressive treatment improves outcome. Angiotensin converting enzyme (ACE) inhibitors should be used. When maximum doses of ACE inhibitors do not control the blood pressure, calcium channel blockers or vasodilators can be used, as needed. Dialysis may be necessary. ACE inhibitors should be continued since there may be delayed recovery of renal function. Renal transplantation can be done successfully.

EMERGENCIES IN INFLAMMATORY MYOPATHIES

Respiratory Muscle Weakness

Significant respiratory muscle weakness may develop in patients with polymyositis or dermatomyositis. Both inspiratory and expiratory muscles may be affected, including the diaphragm. Bulbar weakness results in hoarseness or dysphonia, dysphagia with regurgitation of liquids. Pharyngeal and tongue involvement increases the risk of aspiration. Muscle biopsy should be performed in all cases to confirm the diagnosis. Arterial blood gases will show hypoxia with carbon dioxide retention. Chest radiograph should be done to exclude infection. A simple bedside investigation includes periodic single breath count. Increasing hypoxia, neck muscle weakness (**Figure 5**), falling single breath count, paradoxical breathing is an indication of impending respiratory failure and need for mechanical ventilation. Patient should be started on intravenous Methylprednisolone (1g per day) for 3 to 5 days followed by oral prednisolone 1mg/kg per day. IVIG or plasmapheresis has been successfully used for severe non-responding disease. Biological agents like rituximab have been showed to be useful in a few case reports. Outcome is usually good with most patients regaining power to normal.

Cardiac Disease

Signs of cardiac involvement in PM and DM may be found in more than 70% cases. It is commonly asymptomatic, but can contribute to mortality. The activity of the cardiac disease may be independent of the myositis. The major manifestations include conduction disturbances, arrhythmias, and myocarditis. Less common is congestive heart failure due to myocarditis or fibrous replacement of the myocardium. Symptomatic pericarditis is rare. Although electrocardiographic abnormalities are frequent, most are minor non-specific ST-T wave changes. The MB fraction of creatine kinase is frequently elevated. Treatment includes diuretics for cardiac failure. Dopamine or dobutamine should be added as per clinical requirement. ACE inhibitors should be used as these agents are known to prevent maladaptive remodelling.

Figure 5: Neck muscle weakness in a patient with polymyositis.

CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

Catastrophic antiphospholipid syndrome is a life-threatening complication where multiple thromboses of medium and small arteries in three or more organs can occur over a few days. This is discussed elsewhere.

CONCLUSION

Spectrum of emergencies varies from patient to patient. Superimposed infections, disease flares and adverse reaction to drugs can contribute to morbidity and mortality. A thorough knowledge, appropriate investigations and rapid, accurate treatment of rheumatological emergencies should favourably influence morbidity and outcome.

25.1 Nutrition—Basic Considerations

SV Madhu

INTRODUCTION

The word nutrition comes from the Latin word *nutrire,* to suckle or feed—the primary act of suckling so characteristic of the process of nutrition. Nutrition by definition is the process of nourishment while nutrient is the substance that provides nourishment. Humans not only need nutrients for their nourishment but they also need it in sufficient amount. Nutrients are classified as macronutrient or micronutrient based on daily requirement. Macronutrients include carbohydrates, proteins, fats and minerals like calcium, phosphorus, sodium, chloride, potassium, sulphur and magnesium. Vitamins and minerals that are required in amount less than 100 mg per day constitute micronutrients. Nutrients that cannot be synthesised in body are called essential. While carbohydrates, fats and proteins mainly provide energy and help in tissue building and maintenance, vitamins and minerals mainly support metabolism. Hence, a person must consume a balanced diet to provide all the nutrients in proper measure, known as requirements. A requirement is defined as the lowest continuing intake of a nutrient that will maintain a defined level of nutrition in an individual.

GENERAL PRINCIPLES OF DIETARY RECOMMENDATIONS

Dietary standards are basically the average daily amounts of essential nutrients required to meet the physiological needs of practically all healthy persons in a group with specified characteristics. It is estimated on the basis of available scientific knowledge. These standard values are together called dietary reference intake (DRI). These include estimated average requirement (EAR), recommended daily allowance (RDA), adequate intake (AI) and tolerable upper intake level (UL). A nutrient has either EAR and an RDA, or an AI. When an EAR for the nutrient cannot be determined (and therefore, neither can the RDA), then an AI is set for the nutrient.

Dietary Reference Intakes

Estimated average requirement (EAR): Average daily nutrient intake level estimated to meet the requirement of half the healthy individuals in a particular life stage and gender group.

Recommended dietary allowance (RDA): Average daily nutrient intake level sufficient to meet the nutrient requirement of nearly all (97% to 98%) healthy individuals in a particular life stage and gender group.

Adequate intake (AI): A recommended average daily nutrient intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate, used when an RDA cannot be determined.

Tolerable upper intake level: Highest average of daily nutrient intake level likely to pose no risk of adverse health effects to almost all individuals in the general population. As intake increases above the upper intake level, the potential risk of adverse effects increases.

RDA AND ITS IMPORTANCE

RDA is estimated by first evaluating the EAR for an absorbed nutrient by healthy individual's representative of a sex and age group. An amount is then added as a safety factor which is to compensate for the individual variation and bioavailability of nutrients in commonly consumed foods. When the standard deviation (SD) of the EAR is available and the requirement of the nutrient follows Gaussian distribution, the RDA is calculated as:

$$RDA = EAR + 2SD_{EAR}$$

In cases where SD is not available, a coefficient of variation of 12.5% is assumed and RDA is 25% (+ 2SD) higher than the mean requirement.

Adult men and women differ in their nutrient requirements to a small degree but requirement in the latter group alters significantly during pregnancy and lactation. RDA should be such that it allows maximal rate of growth, prevents biochemical and clinical abnormalities, allows for saturation of enzymes and co-factors, accounts for obligatory losses and builds up the stores. They meet the requirements only when all other nutrients are also provided in optimal amounts. For example, giving fat soluble vitamins according to RDA in the presence of very low fat content food will lead to vitamin deficiency despite being given at RDA levels. However, it must be recognised that RDA is not meant to be used as standard to determine whether or not a given individual requirement has been met, since it is a level above the requirement of most individuals in a given population.

RDA for Indians

The first attempt towards defining the dietary allowances for Indians was made by the Nutrition Advisory Committee of the Indian Research Fund Association [now Indian Council of Medical Research (ICMR)] in 1944. The ICMR constituted an Expert Group in 2008 to revise and update the nutrient requirements and dietary allowances for the Indian population. This is the Sixth Expert Group constituted by the ICMR. The last Group was constituted in 1988. The committee was guided by the newer developments that are published in FAO/World Health Organisation (WHO)/UNU reports and background information generated by research and surveys in India.

Since RDA is the average daily dietary intakes sufficient to meet the nutrient requirement of nearly all healthy individuals, it is necessary to take into account the factors that influence the metabolism of food nutrients. These are: (i) the bioavailability, and (ii) the individual variability.

ENERGY REQUIREMENT

The energy requirement of an individual has been defined by WHO in 1985 as "the level of energy intake from food that balances energy expenditure when the individual has a body size and composition and level of physical activity, consistent with long-term good health, also allowing for maintenance of economically essential and socially desirable activity. In children, and pregnant and lactating women, it includes the energy needs to be associated with the deposition of tissues or secretion of milk at rates consistent with good health".

The energy expended includes the expenditure at rest (basal metabolic rate), physical activity and thermogenesis (specific dynamic action of foods).

Pregnancy and Lactation

Extra energy is required during pregnancy and lactation for the growing foetus and infant, respectively. According to the recent ICMR recommendations, the additional intake of energy is changed to 350 Kcal/day during second and third trimesters of pregnancy, 600 Kcal/day for the first 6 months of lactation and 520 Kcal/day in next 6 months.

DIETARY SOURCES OF ENERGY

Carbohydrates, fats and proteins constitute the sources of energy. Each gram of carbohydrate and protein gives 4 Kcal each while a gram of fat gives 9 Kcal of energy. These three energy sources are to be balanced such that the person receives enough protein for tissue building and maintenance, and sufficient carbohydrate and fat to fulfil the energy requirement.

Carbohydrates

Carbohydrates account for the major part of energy requirement. They are basically made of either simple sugars or complex sugars. Recent scientific evidence considers the unhealthy role of simple sugars. Hence, it is recommended that simple sugars should not account for more than 10% of total energy. A wide range of carbohydrate (55% to 75%) intake should be from whole grains and legumes, vegetables and fruits.

Proteins

The dietary proteins are essential to provide amino acids for the synthesis of body proteins, both structural proteins and biologically active enzymes and other biologically important nitrogenous compounds in the body. Adequate dietary protein is essential during growth in children. In the adult, it is essential for the synthesis of new proteins to replace those, which are being broken down. Additional proteins are also required during pregnancy and lactation for the growing foetus and infant.

There are eight essential amino acids (EAA) that are considered essential as they cannot be synthesised in the body. They need to be provided in proper proportions and in adequate quantities to synthesise tissue proteins in the body. In a diet, proteins are to be provided in proper quantity as well as proper quality. The quality of protein depends on its ability to supply the required amounts of essential amino acids. Animal proteins are generally considered to be of better quality. Egg protein is used as a reference against which the other proteins are compared. Vegetable proteins lack one or the other EAA, such as lysine or methionine. Lysine is the limiting amino acid in most cereals while methionine in the pulses. The biological quality of a mixture of vegetable proteins based on cereals and pulses is only 65% as compared to 100% of egg protein. The safe level of intake in terms of dietary protein is 1.0 g/kg body weight per day. Additional protein requirements of 15 g per day during pregnancy and 25 g per day during 0-6 months of lactation have been recommended.

Fats

Fats being concentrated forms of energy, both optimum and safe intakes need to be mentioned while recommending fats. Source of the fat in diet can be from visible sources or from invisible sources. Visible sources include vegetable oils or animal. A substantial amount of fat is present in cereals, pulses and vegetables which form the invisible fat.

Like amino acids, there are fatty acids that are essential for body and are called essential fatty acids (EFAs). Generally referred as polyunsaturated fatty acids (PUFAs), they include linolic and alpha-linolenic acid.

The minimum amount of fat that should be taken by average Indian adult is 20% of total energy (TE); 10% from visible sources and 10% from invisible sources. However, the fat intake should not exceed 30% of TE. Of these saturated fatty acids should not exceed 10% of TE. 10% of TE should be from PUFA. The remainder should be from monounsaturated fatty acid (MUFA).

Dietary Fibre

Dietary fibre which forms an indigestible and important component of plant foods were never considered as source of energy. Some dietary fibres undergo fermentation in the colon and yield short chain fatty acids. These are used as source of energy by the colonic cells and by the liver. Up to 2.6 Kcal of energy is derived from a gram of fermentable foods and no energy from non-fermentable fibre. Normally, 70% of fibres are fermentable. Hence, energy conversion factor for fibre is taken as 2.0 kcal/g. The intake of 40 g/2000 kcal may be rationalised in different groups based on recommended energy intake.

MALNUTRITION

A decade ago, in India, malnutrition meant mostly undernutrition. But India now being a country in developmental transition, has come to face the other burden of malnutrition, namely overnutrition. With 10% rural adults and 20% urban adults suffering from overnutrition, India is in nutritional transition as well. Pre-transition undernutrition and post-transition overnutrition are together leading to an emerging double burden of malnutrition.

Undernutrition

Undernutrition has improved compared to post-independence time substantially but the improvement has slowed down with very little improvement in last few years. Though severe clinical forms of protein-energy malnutrition (PEM) and other nutrient deficiencies are reduced to major extent, there are still sub-clinical forms of deficiencies that are persisting. Around 36% of women and 34% of men are still having body mass index (BMI) below normal. More than 50% women (particularly pregnant women) and children suffer from iron deficiency anaemia (IDA). The fight against undernutrition is becoming more and more difficult because for every frank case of nutrition deficiency,

there are dozens of others suffering from subclinical malnutrition who are missed.

Factors causing undernutrition

It is necessary to look into the factors that are responsible for undernutrition in order to fight against it. Factors like Illiteracy and low socioeconomic status were responsible for undernutrition in post-independence India, the same factors are still playing the main role 60 years after independence. Women, especially pregnant women and children are the vulnerable risk groups. Rural areas have more percentage compared to urban, almost double in case of adults according to National Family Health Survey-3 (NFHS-3). In case of children, higher birth order and the nutritional status of mother are also important risk factors. Over that, the never ending cycle of undernutrition leading to infections, which in turn leads to undernutrition, makes the problem more complicated.

Protein Energy Malnutrition (PEM)

Despite various government schemes undernutrition is still a major problem in our country. Among children less than 3 years, there are 45% who are stunted, 23% who are underweight and 40% who are wasted. The problem is more in rural, uneducated and low socioeconomic households. Despite the efforts of various organisations, the problem still persists because of lack of awareness and motivation. Even among adults 36% of women and 34% of men are underweight. With the problem involving well more than one-third of Indian population it will have negative impact on the health and development of the country.

Macromineral Deficiency

Among the macrominerals calcium (Ca^{2+}) deficiency has been the main concern. Other macrominerals are sufficient in the diet and do not cause any deficiency. Although intakes according to previous ICMR (1988) survey have been successful to reduce fracture rates, it has resulted in compromises in stature and restriction in the function of the skeletal system. Human body has the ability to adapt to different levels of intakes of Ca^{2+} and maintain a positive Ca^{2+} balance even at 400 mg per day. This prompted earlier committee to fix 400 mg per day as RDA. Despite more than 50% of the adult population obtaining the RDA level of 400 mg per day, there is evidence of widespread Ca^{2+} depletion as indicated by bone density measurements, particularly in women after repeated pregnancies and lactation. These observations lead to new RDA of 600 mg per day.

Micronutrient Deficiency

Even though micronutrients are required in small amounts, they are essential in various body functions. Hence, even slight deficiency can present profoundly. Moreover, many of these are present in lesser amounts in diet and are easily altered by various cooking practices.

Among minerals iodine and iron deficiencies are important public health problems. Iodine deficiency is the single greatest cause of mental retardation both worldwide and in India. Also iodine deficiency disorders (IDDs) are one of the most important micronutrient deficiency disorders of public health significance in India. Environmental factors and goitrogens in food are the two main factors responsible for deficiency. A study conducted by National Institute of Nutrition (NIN) and Director-General of Health Services (DGHS) in 2003, in 40 districts, revealed that the overall prevalence of total goitre registered a significant decline from 14% to 69% during 1984-94 to 2% to 40% in 2003, especially in the Northeastern regions after universal iodisation. But with focus now on whole spectrum of IDD, 263 out of 324 districts surveyed by DGHS have been labeled as endemic. Iodine deficiency has ceased to be a disease of high altitudes. Also living on the sea coast does not guarantee iodine sufficiency, as significant pockets of iodine deficiency have been reported from the coastal regions too. According to NFHS-3 only half of the children below 5 years live in household using iodised salt, same as reported during NFHS-2. A lack of iodine in the diet can lead to IDD, which can cause miscarriages, stillbirths, brain disorders, and retarded psychomotor development, speech and hearing impairments, and depleted levels of energy in children. Iodised salt effectively will account for only half of RDA and so the food practises should be altered to avoid goitrogens in the food. Hopefully the ban on un-iodised salt by the Government of India (in 2006) will improve the scenario in coming years.

Iron is the other micromineral that poses a public health burden. Around 70% of children, 55% of women and 24% of men are anaemic according to NFHS-3. In a study conducted in slum children, 75% of anaemia responded to iron and 22% to vitamin B_{12}. The situation has actually worsened in children and women compared to NFHS-2 despite various government schemes.

Widespread zinc (Zn) deficiency has been thought as a possible cause for growth failure and morbidity in children according to some available data. But lack of supportive evidence of lowered blood Zn levels and other causes that can manifest as the symptoms assumed to be due to Zn deficiency makes it difficult to attribute them to Zn deficiency specifically.

Vitamin deficiencies are also significant. Although there has been a significant reduction in severe clinical forms of vitamin-A deficiency, it is still a public health problem with 40% to 60% children in developing countries showing inadequate biochemical status of vitamin A. Only 25% of below 3 years children received vitamin A supplementation in last 6 months. Very low intakes, poor bioavailability of pro-vitamin A from the predominantly vegetarian diet and recurrent infections are thought to be the main reasons for widespread prevalence of vitamin A deficiency. While the severe forms of bone disease are no longer prevalent in children now, growing urbanisation, reduced physical activity and low exposure to sunlight has contributed to a spurt of vitamin D deficiency (VDD) as evidenced from low circulating vitamin D levels.

Among water soluble vitamins thiamine, riboflavin, folic acid and B_{12} deficiencies are important concern. According to National Nutrition Monitoring Bureau (NNMB), 40% households meet RDA of thiamine and only 13% do so for riboflavin. According to various studies, it is estimated that the B_{12} deficiency involve up to 30% to 40% of Indian population.

OVERNUTRITION

With increased usage of unhealthy processed foods, decreased usage of time tested traditional diets and increased sedentary lifestyles; India is fast approaching other developing countries

which are becoming more obese. According to NFHS-3, around 9% of adult men and 13% of adult women are overweight. Even rural areas are not behind with 10% of adult population of rural area being overweight. Obesity is becoming a substantial problem among several groups of women in India, particularly women living in urban areas, who are well educated, and those from households with a high standard of living. Approximately 25% in each of these groups have a BMI of 25 or more. Indians already being at risk for obesity and diabetes due to their ethnicity, the rising trend of over nourishment might put more burden compared to what it could do in other developing or developed countries.

Though clear-cut nationwide data are not available on childhood obesity, it is estimated that around 25% of urban children are obese. This is to be taken seriously as these children carry a significant risk of developing diabetes, hypertension, metabolic syndrome and coronary heart disease (CHD) in the future as they grow into adulthood. The percentage of adults, who are malnourished, i.e. both under-nourished and over-nourished, does not vary too much across various states or in urban and rural population. The reason being, as the percentage of under-nourished are decreasing, there is an increase in number of adults who are overweight.

Hence, the planning to correct undernutrition has to consider even the possible problem of overnutrition in future. Unless correct measures are taken regarding proper balanced diet, India might become obesity capital as well apart from already being diabetes mellitus capital.

25.2 Assessment of Nutritional Status

Prema Ramachandran

INTRODUCTION

It is well known that nutritional status is an important determinant of health and modifier of course and outcome of diseases. Nutritional status is normal when the food and nutrient intake of the person is sufficient to meet the requirements for normal physical activity, and physiological requirements for growth and development. Balanced diet and adequate physical activity promote normal nutritional and health status and protect against illnesses due to lack or excess of nutrient intake. Appropriate nutritional care during illness can reduce the severity, shorten the duration of illness, hospitalisation and convalescence. Therefore, assessment of nutritional status of the individual seeking health care should be incorporated as a part of promoting good health as well as clinical management of illness.

Health care seekers are becoming increasingly aware of the importance of nutrition and collect information from individuals about: (i) nutritional status; (ii) appropriate and sustainable diets and lifestyle that will prevent illnesses and protect and promote health; and (iii) dietary management during illness that will provide symptomatic relief and promote rapid recovery.

Undergraduates and postgraduates should have the necessary knowledge and skills for assessment of nutritional status and providing appropriate nutrition advise to the individuals, families and communities for prevention and management of under- and overnutrition and nutrition care during illness and convalescence.

PARAMETERS FOR ASSESSMENT OF NUTRITIONAL STATUS

Major parameters used for assessment of nutritional status are:

- Dietary intake
  - Food frequency method
  - 24-hour recall
- Physical activity pattern
- Clinical assessment of nutritional deficiency signs
- Anthropometric assessment of nutritional status
- Body composition studies using various techniques
- Biochemical assessment.

Assessment of Dietary Intake

Dietary intake of individuals, families and communities vary depending upon their socioeconomic status, dietary habits and customs. Information of nutrient intake will help in identifying factors responsible for under- and overnutrition and micronutrient deficiencies which could have contributed to illness. Illness may modify the dietary intake and aggravate nutritional deficiencies.

Food frequency questionnaire provides a relatively rapid and easy method of assessing food consumption of the individual, including meal and dietary patterns, specific foods avoided or preferred. Food frequency questionnaire will not give any idea about the quantities in which the food stuffs are consumed which is an important determinant of deficiency or excess.

Diet history using 24-hour recall is an excellent tool to obtain information on the family cooking patterns, intra-family distribution of food and individual's dietary intake. Diet survey using 24-hour dietary recall should not be done on the day following holidays or festival or fast days because dietary intake on these days will not be representative. Single day 24-hour dietary recall cannot be taken as accurate representation of dietary intake of the individual but if repeated over time may provide useful information whether nutrition counselling has resulted in on dietary modifications of the individual.

Available data from diet surveys in India indicate that Indian diets remain predominantly cereal-pulse based. Dietary intake in poor segments especially in children and adolescents are below the requirement; as a result undernutrition rates are high. Low intake of vegetables and fruits, poor bioavailability of iron, and lack of universal use of iodised salts are responsible for micronutrient deficiencies being major public health problems even today. Even segments of population with no economic constraints, do not consume diversified balanced diets with adequate intakes of fruits and vegetables, animal/dairy products. In some urban affluent segments there is an increase in consumption of junk food, rich in carbohydrates and fat, resulting in rapid increase in obesity in these groups. Assessment of dietary intake and appropriate advise is important for maintenance of optimal health and combating over- and undernutrition.

Physical Activity Pattern

Physical activity pattern is emerging as an important determinant of nutritional status both in urban and rural areas. Earlier majority of men and women in rural and urban areas were moderately active. However, increasing access to mechanised transport, access to water and fuel in the vicinity of the house hold and increasing mechanisation of the occupational activities have resulted in a steep decline in physical activity. This in turn has resulted in substantial reduction in energy requirements of the individual. Steep reduction in physical activity and relatively unchanged energy intake have been identified as the major factors responsible for rising obesity rates in urban and rural populations. In some urban affluent groups, increased intake of energy dense junk food and sedentary lifestyle are emerging as major factors associated with overnutrition.

Nutrition surveys carried-out by the National Nutrition Monitoring Bureau (NNMB) has shown that by mid nineties there had been a steep reduction in physical activity not only in urban but also in rural areas (**Table 1**). Health education

about exercise to become a part of daily routine to promote muscle and bone health and prevent development of adiposity in all age groups is critical for prevention of overnutrition and associated health hazards. As and when any person seeks health care, the opportunity should be utilised to assess nutritional status and physical activity and advise appropriate lifestyle modifications.

Table 1: Physical Activity Pattern in Rural Adults Based Upon NNMB Survey 1994-95

Activity status	Men		Women		Total	
	No.	%	No.	%	No.	%
Sedentary	1349	33.3	2765	62.7	4114	48.6
Moderate	2650	65.5	1632	37.0	4282	50.6
Heavy	48	1.2	14	0.3	62	0.8
Pooled	4047	100.0	4411	100.0	8458	100.0

NNMB = National Nutrition Monitoring Bureau.

Clinical Assessment of Nutritional Status

In the last century, clinical assessment of nutritional deficiency signs was a very important component of assessment of nutritional status. However, with improvement in dietary intake and better access to health care, there has been a steep decline in the prevalence of clinical signs of deficiencies. Pellagra, scurvy, keratomalacia are no longer seen. Even in tertiary hospitals, kwashiorkor, and marasmus are rarely seen. Glossitis, angular stomatitis (suggestive of vitamin B complex deficiency), Bitot's spots (vitamin A deficiency) are seen in less than 1% of children and adults. There has been a steep decline in goitre even in the erstwhile goitre belt. Even though clinical forms of macro- and micronutrient deficiencies have become uncommon, sub-clinical biochemical deficiencies continue to be common.

It is a matter of concern that unlike all other nutritional deficiencies, there has not been any change in the prevalence of anaemia. Clinical signs of anaemia are non-specific (easy fatiguability, pallor, oedema feet) and do not revert soon after therapy, e.g. spoon shaped nails. It is not possible to clinically assess severity of anaemia and response to iron therapy; so estimation of of haemoglobin by cyanmethaemoglobin method is the best method for diagnosis of anaemia and assessing response to therapy. Majority of Indians irrespective of age, sex and socioeconomic status are iron deficient and anaemic; in view of this whenever any person seeks health care for any reason, they should be screened for anaemia and appropriate treatment provided for all anaemic persons.

Anthropometric Assessment

Anthropometric assessment is one of the most widely used methods for assessment of nutritional status both at the community level and for the individuals because of the relative ease and reproducibility of measurements, availability of standards based on normal population for comparison and demonstrated association between abnormal measurements and clinical illnesses. In the past when undernutrition was the major problem, weight and height were the most widely used measurements for the assessment of nutritional status. Height is the index that reflects the cumulative impact of past undernutrition. Weight is the index that reflects partly the cumulative impact of past undernutrition (because stunting is associated with lower body weight) and partly current nutritional status [low body mass index (BMI) for the current height is associated with lower body weight]. With the emergence of dual nutrition burden, BMI (weight in kg/height in m^2) has been increasingly used for the detection of both under- and overnutrition, especially in developing countries where stunting is common. In children BMI varies with age; World Health Organisation (WHO) has published the standards for BMI for age from 0 to 5 years in 2006 and 5+ to 18 years in 2007 and recommended that BMI for age which takes current height, weight and age into account and assesses current energy deficit or excess, should be used for the assessment of nutritional status, detection of both under- and overnutrition in children. India has accepted the WHO standards (2006 and 2007) for height, weight and BMI for age for assessment of under- and overnutrition in infants, children and adolescents. For adults, BMI has long been used as an indicator for both over- and undernutrition.

Measurement of length/height

In infants and children who cannot stand erect recumbent length is measured using either a stadiometer or an infantometer (**Figure 1**). In the past, height was measured using anthropometry rod or stadiometer. In recent years when almost all health care institutions have a vertical wall and good cement flooring, there is a greater tendency to use simple wall mounted tape instruments to measure height in children and adults in hospital settings. The instrument is hung on the wall exactly two meters from the floor. To measure height accurately, the person is made to stand erect with back of heels, knees, buttocks, shoulder and head touching the wall. The head is to be positioned in Frankfurt plane (lower margin of the orbital fossa in the horizontal line with the external auditory meatus) and the horizontal limb of the instrument is brought down, so that it lies on the top of the head. The reading at the horizontal red mark on the tape is the height of the person.

Figure 1: Measuring length in infants.

Height is an excellent indicator of cumulative past undernutrition; serial height measurements in children can indicate whether they are growing according to their trajectory or deviating from it. Data from national surveys of India indicate that average height in men and women are about 160 cm and 150 cm, respectively and about 11% of women have height below 145 cm. Low birth length, stunting in childhood (nearly half of the pre-school children are stunted) and adolescence are major factors responsible for the low adult height in Indians.

Measurement of weight

During the last century accurate beam balances were used for measurement of weight in clinical settings. These balances were heavy and could not be shifted readily from one place to another. With the advent of electronic balances, it has became possible to measure weight with 100 g accuracy using a battery operated, relatively inexpensive, light and readily portable balances (**Figure 2**). In the past when undernutrition was the most common nutritional problem in the country, weight was the most widely used measurement for assessment of nutritional status in adults and children because it provided some insight into past and current energy deficiency. Underweight individuals are more prone for infections and infections can result in further deterioration in body weight. Nutritional support during illness and convalescence can limit and reverse the weight loss associated with illnesses. Data from national surveys indicate that mean weight in men and women are 45 and 53 kg, respectively. It is estimated that about half the children and a third of adult men and women are underweight in Indian population.

Figure 2: Measuring weight on an electronic weighing machine.

Computation of BMI

With the emergence of dual nutrition burden it has become essential to assess current energy deficiency and excess; BMI which provides this information has been increasingly used for assessment of nutritional status. Low BMI is associated with increased susceptibility to infections; high BMI is associated with increased risk of cardiovascular diseases. Earlier the computation of BMI was considered difficult in clinical settings; however, with the ready availability of calculators (even in mobile phones), it has become very easy to compute BMI. In adults, cut-off points used are less than 18.5 for undernutrition and more than 25 for overnutrition. In children BMI varies with age; WHO's BMI for age chart can be used to assess whether the child is undernourished or over-nourished.

Data from NFHS-3 indicate that if BMI is used as the indictor for the assessment of nutritional status, about 17% of pre-school children and a third of men and women are under-nourished; about 2% of pre-school children and 9% of men and 13% of women are overnourished (**Figure 3**). India has entered the dual nutrition burden era; all practising physicians should assess the current nutritional status using BMI and provide appropriate advise regarding dietary intake and physical activity to all persons seeking health care.

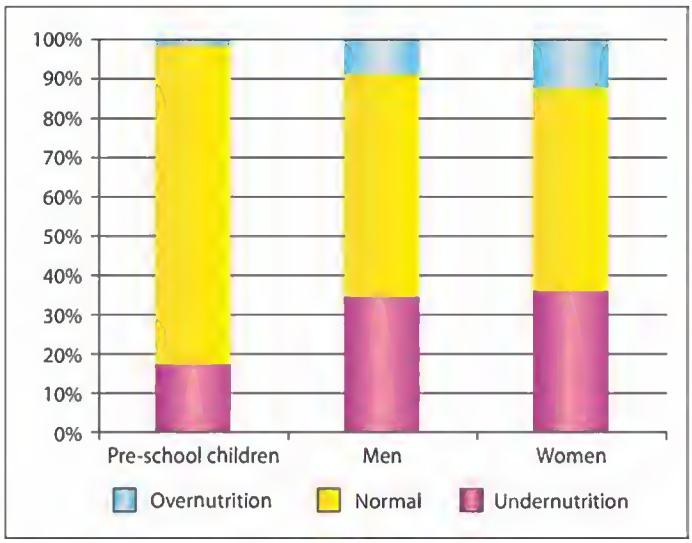

Figure 3: Nutritional status of children and adults-NFHS 3.

Waist circumference

With the emergence of non-communicable diseases as an important cause of morbidity in our country, it has become very important to measure waist circumference as an index of central adiposity. This correlates very well with insulin resistance and is a good indicator of the risk of diabetes and cardiovascular diseases. It is measured as the smallest circumference mid way between iliac crest and lower end of rib cage in standing position and at end of expiration. Waist measurements of 90 cm or above in males and 80 cm and above in females indicate central obesity in Asian Indians.

Assessment of Body Composition

The Indians have higher body fat for a given BMI as compared to Caucasians; higher adiposity in Indians begins in infancy and childhood. Both amount and distribution of the adipose tissue have been shown to influence the risk of cardiovascular diseases; therefore, increasing attention being paid to fat mass and its distribution. Earlier circumferential measurements (mid arm circumference, waist and hip circumferences and waist/hip ratio) and measurement of fat fold thickness (triceps, biceps, supra-iliac and subscapular fat folds measured using Harpenden's calipers) were commonly used for the assessment of fat mass and its distribution. Fat fold measurement requires a trained and skilled person; this has come in the way of widespread use of this relatively simple technique. In recent years, bioelectrical impendence measurement has been widely used in clinical settings for the assessment of total fat. Fat mass estimation by bioelectrical impedance assessment (BIA) when combined with the measurement of mid arm, waist and hip circumference can be used to differentiate overall, truncal and abdominal obesity. Epidemiological studies have explored the relative risk of diabetes and cardiovascular diseases with overall adiposity, truncal adiposity and abdominal adiposity, and also as between subcutaneous, intraperitoneal and retroperitonal fat accumulation in abdominal adiposity. Available data suggest

that abdominal adiposity is a part of metabolic syndrome which is associated with increased risk of both type 2 diabetes and cardiovascular disease risk.

Biochemical Assessment of Nutritional Status

Ideal biochemical test should be non-invasive, easy to carryout, specific, sensitive and preferably inexpensive. Such ideal tests are very few. In the development of any disease associated with deficiency or excess of nutrients, it is logical to expect that biochemical changes precede clinical manifestations. Biochemical tests can, therefore, expected to provide early warning of impending clinical problems. Biochemical tests in blood and urine can help diagnosis of the deficiency at the sub-clinical stage and confirm the clinical diagnosis. It has been reported that biochemical evidence of many vitamins and minerals have been seen in nearly half the apparently normal children and adults. It may not always be possible to get good correlations between biochemical tests, dietary intake and clinical parameters because of the wide range of normal biochemical values, varied rates of change of biochemical parameters, clinical deficiency and functional impairment. Inspite of these inherent limitations, biochemical tests have been widely used for the assessment of subclinical macro- and micronutrient deficiencies and excesses and risk of or confirmation of clinical problems. While isolated single biochemical estimation may not be of much use in the assessment of nutritional status, well chosen tests combined with dietary history, physical activity patterns and clinical examination findings provide complete information on nutritional status of the individual. Commonly used biochemical tests for the assessment of nutritional status and associated disease risks are dealt with in the respective chapters.

CONCLUSION

India is currently in the midst of socioeconomic, demographic, lifestyle, nutritional and health transition. Undernutrition continues to affect large segments of the population and is associated with increased risk of morbidity due to infections; simultaneously obesity and associated risk of non-communicable diseases are emerging as important public health problems, especially, among affluent segments of the society. Data from India also indicate that undernutrition in early life, followed by increased energy intake and sedentary lifestyle predispose to overnutrition and risk of non-communicable diseases during adult life. Physicians and programme managers have to play a critical role in combating the dual nutrition and disease burden and enable the country to achieve rapid improvement in health and nutritional status of the population through: (i) assessment of nutritional status of the community through appropriate screening; (ii) appropriate nutrition and lifestyle counselling for health promotion and health protection; and (iii) promoting synergy between health and nutrition services.

Assessment of nutritional status is an important component of both public health interventions and care of individuals seeking health care. Ideally nutritional assessment should be carried out periodically in all individuals and more often during vulnerable segments of population such as children, adolescents, pregnant and lactating women and elderly citizens. Our population and the health systems is still not geared to such routine periodic assessment and appropriate counselling for health promotion and early detection and effective management of nutritional deficiencies and excesses before clinical problems arise. In view of this, assessment of nutritional status should be carried out as and when there is an opportunity—as a part of community based nutrition surveys—and when any person seeks health care. Once assessment is done appropriate advice should be given depending upon their nutritional status.

25.3 Protein Energy Malnutrition

Piyush Gupta

INTRODUCTION

Adequate food and nutritions are essential for proper growth and physical development to ensure optimal work capacity, normal reproductive performance, adequate immune mechanism, and resistance to infections. Inadequate diet may produce several forms of malnutrition in children, the most important being the protein-energy malnutrition (PEM).

Acute undernutrition results in wasting and occurs when food consumption is suddenly and severely reduced. *Chronic undernutrition* occurs when long-term food consumption is insufficient to meet the energy requirements on a daily basis for daily energy expenditure. It is usually assessed in terms of body measurements: in adults – thinness; in children – stunting.

More than one-fourth of children under five years of age worldwide (about 150 million) are underweight while about one-third (182 million) are stunted. Geographically, more than 70% of PEM children live in Asia, 26% in Africa and 4% in Latin America and the Caribbean. The prevalence of stunting has fallen in developing countries from 47% in 1980 to 30% in 2006-07, although progress has been uneven according to regions. One key target of the United Nations Millennium Development Goals is to reduce the prevalence of underweight among children younger than 5 years by half between 1990 and 2015. However, worldwide, underweight prevalence is projected to decline from 27% in 1990 to 18% in 2015. The Asian data on overall prevalence of PEM is shown in **Table 1**.

Table 1: Prevalence of Childhood Malnutrition

Country	Per cent of infants born with low birth weight	Per cent of children under five years suffering from malnutrition			
		Underweight			
		Moderate	Severe	Wasting	Stunted growth
Afghanistan	–	39	12	7	54
Bangladesh	22	46	–	16	36
Bhutan	15	19	3	3	40
China	2	7	–	–	11
India	28	46	–	19	38
Maldives	22	30	7	13	25
Myanmar	15	35	8	9	34
Nepal	21	45	10	12	43

According to National Family Health Survey-3 (NFHS-3) (2005-06) report, 43% of children under five years of age were underweight, and almost half (48%) were stunted (**Figure 1**).

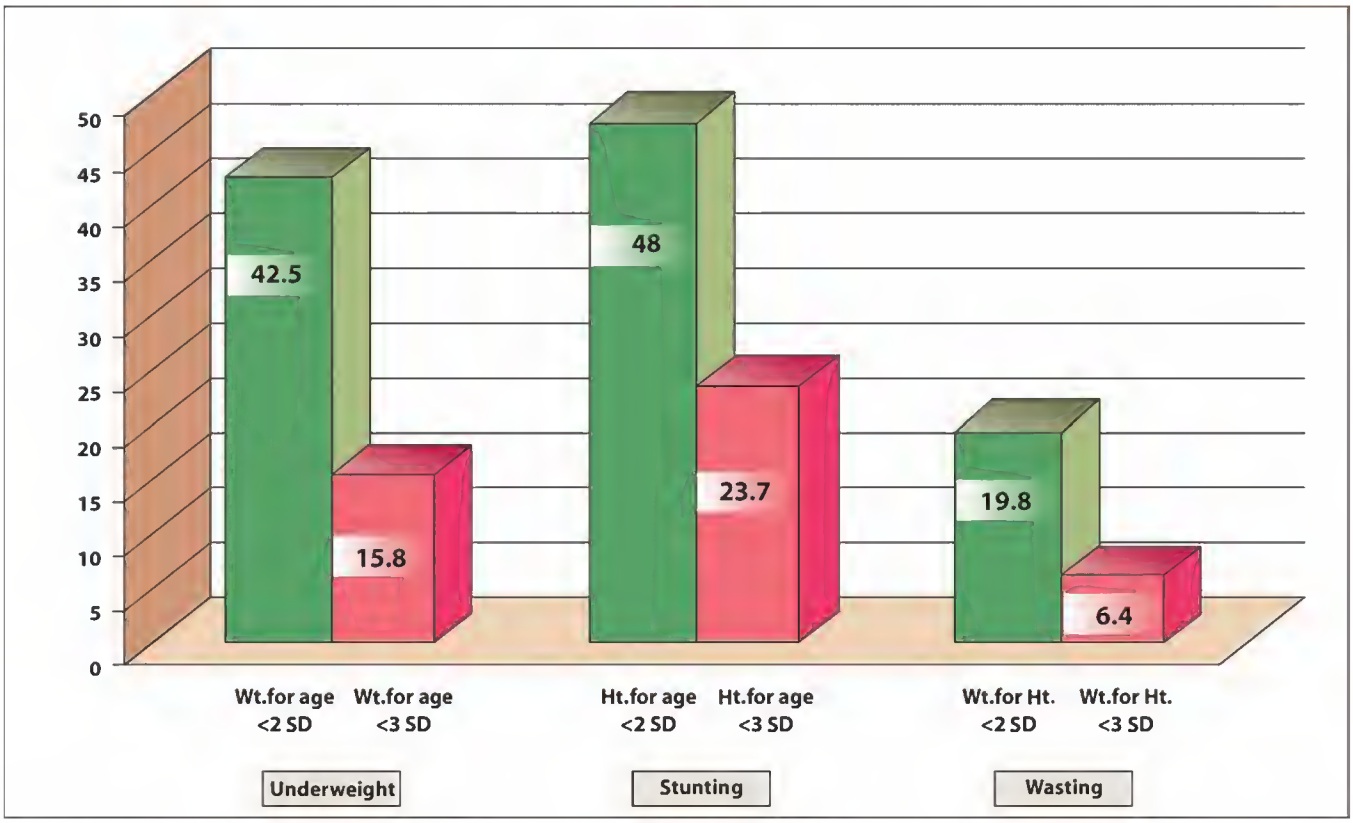

Figure 1: Nutritional status of children under five years of age in India according to National Family Health Survey-3.

Wasting (weight- for height <80% or <2SD of expected) was less prevalent, affecting 20% of children under five years of age.

Nutritional Status of Adults

Data on nutritional status of adults are determined by body mass index (BMI), which is expressed as follows:

$$BMI = Weight\ (Kg)/Height\ (m^2)$$

A cut-off point of BMI of 18.5 is used to define thinness or acute undernutrition and a BMI of 25 or above indicates overweight or obesity. However, there is a strong justification for using BMI cut-offs of 23 for defining overweight in Indian population. At any given BMI, Asians have higher body fat percentage as compared to other ethnic groups. **Table 2** presents the nutritional indicators of adults in India. More than one-third (36%) of women have a BMI below 18.5, indicating a high prevalence of malnutrition.

Table 2: Nutritional Status of Indian Adults (15-49 Years of Age)*

Nutritional status	BMI	Per cent females	Prevalence males
Obese	>30	2.8	1.3
Overweight	25–29.9	9.8	8.0
Normal	18.5–24.9	51.8	56.5
Mildly thin	17–18.4	19.7	20.4
Moderately/severely thin	<17	15.8	13.8

**Source: National Family Health Survey.*
BMI = Body mass index

EPIDEMIOLOGY OF PROTEIN-ENERGY MALNUTRITION

The proportion of children who are stunted or underweight increases rapidly with the child's age through age 20 to 23 months. Overall, girls and boys are about equally undernourished. Undernutrition is generally lower for first births than for subsequent births and consistently increases with increasing birth order for all measures of nutritional status (**Table 3**).

Table 3: Factors in Causation of Protein-energy Malnutrition

Short birth interval
Mother's education
Underweight mothers, especially BMI of less than 18.5
Lack of breastfeeding in initial 6 months after birth
Bottle feeding with unclean bottle and nipples
Dietary practices and taboos in families and society
Poverty
Recurrent infections diarrhoea, pneumonia

BMI = Body mass index.

These factors not only precipitate PEM but also decrease the immunity resulting in repeated infections and vicious cycle of malnutrition.

CLASSIFICATION OF PROTEIN-ENERGY MALNUTRITION

PEM may be classified according to the severity, course and the relative contributions of energy or protein deficits. Severity classifications based on anthropometric measurements, mainly weight and height are suggested.

Weight for Age Classifications

Gomez's is an international classification that considers a weight of more than 90% of what was expected for that age (median or 50th percentile) as normal. Weight for age groups between 76% to 90%, 61% to 75% and less than or equal to 60% are classified as grades I, II and III malnutrition, respectively. Indian Academy of Pediatrics (IAP) considers a weight of more than 80% of median for that age as normal. Grades of malnutrition are grade I (71% to 80%), II (61% to 70%), III (51% to 60%) and IV (<50%). The disadvantage of weight-based classifications is that these do not take in account the child's height. The weight is also dependent on height, besides the build; thus, children who are short statured (not necessarily because of nutritional deprivation) are also misclassified as PEM by these classifications.

Current Nomenclature

The above classifications measure undernutrition and are based on weight for age alone. However, it is important to distinguish undernutrition from *wasting* (deficits in weight-for-height) and *stunting* (height-for-age).

1. *Wasting* indicates a deficit in tissue and fat mass and may result either from failure to gain weight or from actual weight loss. It usually signifies acute onset of malnutrition.
2. *Stunting* signifies accumulated consequences of retarded growth over some years and generally points towards a chronic course of malnutrition. It may also be a residue of past malnutrition or could be due to non-nutritional disorders, like genetic short stature or endocrinal disorders.
3. *Wasting and stunting* are frequently coexistent and a greater and disproportionate reduction in weight as compared to reduction in height indicates *acute on chronic PEM.*

World Health Organisation (WHO) classification of undernutrition is based on this nomenclature. This classification is used for assessing the magnitude of malnutrition amongst children under five years of age in national health programmes (**Table 4**).

Table 4: WHO Classification for Undernutrition

	Moderate undernutrition	Severe undernutrition
Symmetrical oedema	No	Yes[a] Oedematous malnutrition
Weight for height (measure of wasting)	SD score[b] -2 to -3 (70-79% of expected[c]) Wasting	SD score < -3 (< 70% of expected) Severe wasting
Height for age (measure of stunting)	SD score[b] -2 to -3 (85-89% of expected[c]) Stunting	SD score < -3 (<85% of expected) Severe stunting

a = This includes kwashiorkor and marasmic kwashiorkor.

$$b = SD\ score = \frac{observed\ value - expected\ value}{Standard\ deviation\ of\ reference\ population}$$

c = Median (50th percentile of NCHS standards).
WHO = World Health Organisation; SD = Standard deviation; NCHS = National Child Health Survey.

CLINICAL FEATURES

Clinical features of malnutrition depend on the severity and duration of nutritional deprivation, the age of the undernourished subject, and the presence or absence of associated

infections. Severely malnourished subjects form only tip of the iceberg. A much larger number of subjects suffer from mild-to-moderate nutritional deficit. Key features of kwashiorkor and marasmus are listed in Table 5.

Table 5: Characteristic Clinical Features of Protein-energy Malnutrition

	Essential Features	Other Features
Kwashiorkor	Growth retardation Oedema Psychomotor changes	Infections Hair and skin changes Hepatomegaly
Marasmus	Wasting	Infections, irritability

Marasmus

A marasmic child is markedly wasted with body weight less than 60% of the expected weight for the age. The child appears disproportionate with long body, thin limbs and unduly large head. Buttocks are flattened with wrinkling of skin over the front of thighs. The scapulae look winged. Abdomen appears distended. The fat in the adipose tissues is severely depleted because it is used up for providing energy. The contour of atrophic muscles is evident under the thin and wrinkled skin. Loose folds of skin are prominent over the glutei and the inner side of thigh. The buccal pad of fat is preserved till the malnutrition becomes extreme. The skin appears dry and inelastic. The hair is hypopigmented. Child appears all bones and skin and the bony points appear unduly prominent (Figure 2). The child usually appears alert.

Kwashiorkor

Marked growth retardation, psychomotor changes, and oedema of dependent parts are three essential clinical features of Kwashiorkor (Figure 3). The face appears moon-shaped and puffy. The trunk is affected to a lesser extent. In a previously malnourished child, oedema may be precipitated by debilitating illnesses, such as measles or diarrhoea. The child becomes lethargic, listless and apathetic. He takes little interest in the environment and does not play with toys. Appetite is impaired and it is difficult to give oral feeds. The hair becomes thin, dry, brittle and hypopigmented. The liver is enlarged due to fatty infiltration. Skin becomes erythematous, hyperpigmented, and hyper-keratotic. The epidermis peels off in large scales, exposing tender raw area underneath. It appears like old paint flaking off a wooden surface. Petechiae and purpura appear in severe cases.

Figure 3: Children showing various features of Kwashiorkar.

Figure 2: Child showing features of Marasmus.

Kwashiorkor results from an imbalance between the production of free radicals and their safe disposal. Various *noxae* to which these children are exposed produce an oxidative toxic stress which leads to excess of free radical, peroxide and carbonyl formation. These toxic products cause damage as the mechanisms for their disposal are also compromised. The free radical damage is much more in kwashiorkor than marasmus. Red cell glutathione, serum ferritin, and proportion of red cell NADP in oxidised form are therefore markedly different in 2 conditions. Free radicals cause cell membrane damage that leads to increased permeability and hence oedema of kwashiorkor. The free radical theory (Michael Golden) may explain the whole range of manifestations of kwashiorkor whereas the protein deficiency theory just accounts for oedema.

Associated Nutritional Deficiencies

PEM is usually associated with multiple nutritional deficiencies. Anaemia may occur due to iron, protein, vitamin B_{12} or folate deficiency. Ariboflavinosis is common. Vitamin A deficiency is almost universal in children with severe PEM. Vitamin C deficiency manifests as bleeding gums, or subperiosteal haemorrhage. Despite underlying vitamin D deficiency, clinical manifestations of rickets may not be overt, since rickets is a disease of growing bones.

CHANGES IN BODY COMPOSITION

In a severely malnourished child, muscle mass is severely compromised, reducing by up to 70%. Body fat may be reduced

by up to 95%. Total bone mass is reduced with osteoporosis and delayed ossification. Total body water in malnourished children is increased to 70% to 80% of body weight.

Metabolic Alterations

Basal metabolic rate (BMR) is reduced by 30% and energy expenditure due to activity is very low. Heat generation and heat losses are affected so that the child may behave like a poikilotherm. These factors predispose to hypothermia. Cardiac output and stroke volume are reduced. Blood pressure is low and renal perfusion is compromised. Glomerular filtration rate and renal plasma flow are reduced. Insulin levels are reduced and the child has glucose intolerance. Cortisol and growth hormone levels are increased.

PRINCIPLES OF PROTEIN-ENERGY MALNUTRITION MANAGEMENT

The patient is evaluated for the severity of PEM, presence or absence of systemic infections, other nutritional deficits, such as vitamin deficiencies or anaemia, and fluid and electrolyte disturbances.

Moderate Malnutrition

These children are best treated in their own home surroundings, because domiciliary treatment of malnourished children by their mother has an inbuilt advantage of practical health education. The parents are advised to increase the food intake of the child by all available means. The child should receive adequate calories and proteins in the diet, which should be prepared from the locally available and inexpensive food.

Recurrence of malnutrition is infrequent among children treated in their own homes. After the initial treatment, these children should be kept undernutritional surveillance to detect and prevent deterioration in their nutritional status, and as early as possible to promote their nutrition and health by prompt remedial measures.

Severe Protein-Energy Malnutrition

Severely malnourished children should be treated in the hospital. Vigorous and prompt treatment is necessary to save them from death or irreversible functional handicaps. With appropriate treatment (as per WHO guidelines), the usual case fatality rate of 30% to 50% can be reduced to less than 5%. The 10 steps for the management of severe malnutrition are listed in **Figure 4**. These steps are accomplished in two phases: an initial stabilisation phase where the acute medical conditions are managed; and a longer rehabilitation phase. Sequential management of severe PEM is also depicted.

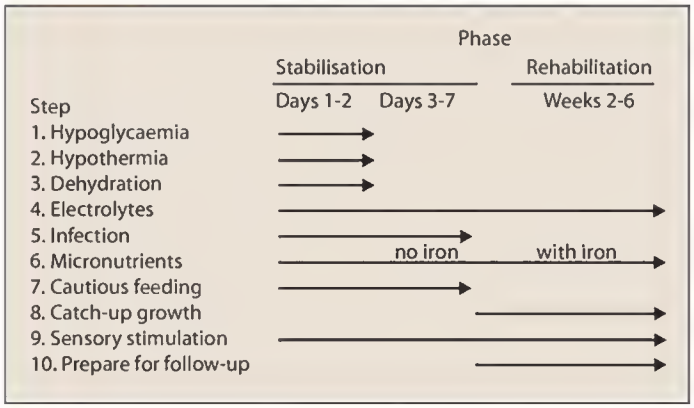

Figure 4: Sequential approach to management of severe PEM.

The ten steps to treat severe PEM

Step 1. Treat/prevent hypoglycaemia: By supplementing with oral glucose. Formula feeds are started after this.

Step 2. Treat/prevent hypothermia: Marasmic infants are prone to become hypothermic and require rewarming by warm blanket or other means (Kangaroo technique).

Step 3. Treat/prevent dehydration: It is difficult to evaluate dehydration in children with severe malnutrition. Thus all children with severe PEM and diarrhoea should be presumed to have some dehydration and given low osmolarity ORS. Intravenous therapy should only be given for shock.

Step 4. Correct electrolyte imbalance: All severely malnourished children have excess body sodium even though plasma sodium may be low. Therefore, only low osmolarity ORS should be given when rehydrating. Food should be prepared without salt. The child needs to be given extra potassium (3-4 mmol/kg per day) and magnesium (0.4-0.6 mmol/kg) for at least 2 weeks.

Step 5. Treat/prevent infection: The child should be clinically examined for the presence of infections and adequately treated. Antibiotics should be given routinely.

Step 6. Correct micronutrient deficiencies: All severely malnourished children should receive: vitamin A orally on Day 1 (200,000 IU for age >12 months; 100,000 IU for 6-12 months and 50,000 IU for 0-5 months) unless there is definite evidence that a dose has been given in the last month. The following micronutrients should be given on daily basis for at least 2 weeks: (i) multivitamin supplement; (ii) folic acid 1 mg per day (give 5 mg on Day 1); (iii) zinc 2 mg/kg per day; and (iv) copper 0.3 mg/kg per day.

Blood transfusion is required if haemoglobin is less than 4 g/dL and/or if there is respiratory distress with a haemoglobin of 4 to 6 g/dL. In mild or moderate anaemia, oral iron should be given after controlling the infection.

Step 7. Start cautious feeding: In the stabilisation phase a cautious approach is required because of the child's fragile physiological state and reduced homeostatic capacity. Feeding in the stabilisation phase should be started as small, frequent feeds of low osmolarity and low lactose. These can be given as oral or nasogastric (NG) feeds. One should start with 100 kcal/kg per day of calories and 1-1.5 g/kg per day of proteins, in the beginning. The fluid intake should be restricted to 130 mL/kg per day of fluid (100 mL/kg per day if the child has oedema). Calculations are made on the basal recorded weight and this can lead to both initial weight gain or weight loss.

Breastfeeding should be continued; in addition, rational food supplement formula is to be added.

Step 8. Achieve catch-up growth: The rehabilitation phase starts after a week and requires a vigorous approach to feeding to achieve rapid weight gain of >10 g/kg per day. At this time gradually switch from one formula to other richer formula diet. Modified family foods can be used provided they have comparable energy and protein concentrations.

Step 9. Provide sensory stimulation: Provide tender loving care; a cheerful, stimulating environment and maternal involvement.

Step 10. Prepare for follow-up after recovery: Return of appetite, gain in body weight with loss of oedema, disappearance of hepatomegaly and rising serum albumin are the early signs of recovery. A child who has achieved 90% weight-for-length is considered to have recovered. The child is still likely to have a low weight-for-age because of stunting. Good feeding practices and sensory stimulation should be continued at home. Educate parents about feeding and maintain a close follow-up plan.

Treatment of associated conditions

Associated conditions may require appropriate treatment with vitamin A, zinc supplementation, mebendazole or anti-tuberculosis treatment wherever required.

PREVENTION OF PROTEIN-ENERGY MALNUTRITION

Improvement of nutrition of people is an essential component of primary health care. It is necessary to keep the community under nutritional surveillance, to take appropriate decision to prevent malnutrition and promote health and nutrition in people. The nutrition can be improved by adopting two major strategies, *viz. nutritional planning*, and *direct nutrition and health interventions*. Both strategies need to be carried out concurrently, since the former results in long-term permanent benefits, and the latter provides immediate relief to those who need help. Concurrent nutritional surveillance is essential to monitor the impact of planning and intervention, and to introduce nutritional supplementation to bring about an immediate change in the nutritional status of the community.

25.4 Water Soluble Vitamins

Milind Y Nadkar

INTRODUCTION

Water soluble vitamins include vitamin B complex and vitamin C. They act as co-enzymes for various biochemical reactions. Vitamins present in food are absorbed into the portal vein and transported to the liver. Excess amounts are excreted in urine. There is little storage of these vitamins and they need to be constantly supplied in the diet. Excess intake is generally well tolerated because of excretion in urine, except for toxicity reported with large doses of niacin, pyridoxine, and vitamin C.

THIAMINE (VITAMIN B_1)

Thiamine was the first B vitamin to be identified; hence termed as vitamin B_1. The active form is thiamine pyrophosphate (TPP). It acts as a co-enzyme in decarboxylation and transketolation reactions involved in carbohydrate metabolism and synthesis of adenosine triphosphate (ATP). It is also believed to play a part in nerve conduction.

Dietary sources include whole grains, nuts, meat, and legumes. Milled and polished rice is deficient in thiamine. Recommended daily allowance (RDA) for adults is 1.2 mg per day.

Aetiology—Thiamine Deficiency

The most common cause of thiamine deficiency is poor dietary intake due to poor socioeconomic conditions or alcoholism. Consumption of polished rice or other highly refined foods such as sugar and wheat flour as staple diet leads to thiamine deficiency. Part of thiamine is also lost by faulty cooking habits. High carbohydrate intake increases need for thiamine for its metabolism. Vitamin/energy ratio of 0.5 mg/1000 cal should be maintained in the diet. Carbohydrate repletion without adequate thiamine can precipitate acute thiamine deficiency and causes Wernicke-Korsakoff syndrome. Chronic illnesses like cancer and chronic dialysis are associated with thiamine deficiency.

Clinical Features

Mild deficiency in early stages produces non-specific symptoms like irritability and anorexia.

The clinical syndrome of prolonged thiamine deficiency is beriberi. It is classified as dry beriberi and wet beriberi, although there is considerable overlap. Wet beriberi is characterised by high output cardiac failure due to impaired myocardial energy metabolism. Patient presents with oedema, dyspnoea, palpitations, tachycardia, wide pulse pressure, pulmonary crepitations, hepatomegaly and ascites. Dry beriberi presents as symmetric, motor and sensory peripheral neuropathy. Legs are more severely affected than hands. Symptoms include pain, paraesthesias, numbness of extremities and difficulty in rising from squatting position. On examination, there is glove and stocking type of anaesthesia, motor weakness and diminished reflexes.

Wernicke's encephalopathy is seen in alcoholic patients with thiamine deficiency. The classic clinical triad is ophthalmoplegia, ataxia and confusion. Horizontal nystagmus is also present. The chronic state is characterised by anterograde amnesia and confabulations. It is called Korsakoff's psychosis.

Laboratory diagnosis of thiamine deficiency is made by the assay of erythrocyte transketolase activity or by thiamine concentration in serum or urine.

Treatment

In severe deficiency, with cardiovascular and/or neurological impairment, 100 mg of thiamine is given per day parenterally, for seven days, followed by 10 mg per day until recovery. Cardiovascular improvement occurs in 12 hours; ocular palsies improve within 24 hours. Ataxia improves slowly. Psychosis may persist for several months or may be permanent.

Glucose infusion can precipitate Wernicke's encephalopathy in alcoholic patients. Hence, thiamine should be administered to all alcoholic patients prior to parenteral glucose.

Toxicity

Anaphylaxis has been reported after high doses of thiamine given parenterally. No adverse effects have been recorded from high doses of thiamine in food supplements.

RIBOFLAVIN (VITAMIN B_2)

Riboflavin is essential for the metabolism of carbohydrates, fats, and proteins. The active forms of riboflavin are flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). The FMN and FAD serve as prosthetic groups of several oxidoreductase enzymes, known as flavoproteins.

Dietary sources are milk and milk products, legumes, meat, fish and eggs. The RDA is 1.1 to 1.3 mg per day.

Aetiology—Riboflavin Deficiency

It is usually seen in conjunction with deficiencies of other B vitamins. It is widely prevalent in populations of lower socioeconomic group due to poor intake of vitamins. Children, pregnant and lactating women are susceptible to riboflavin deficiency due to increased demands. Chronic illnesses like tuberculosis (TB), cancer and alcoholism also lead to riboflavin deficiency. Chlorpromazine inhibits conversion of riboflavin to active form.

Clinical Features

Clinical manifestations of riboflavin deficiency are non-specific and not life-threatening. Mucocutaneous lesions include angular stomatitis, glossitis, cheilosis and magenta-red tongue or bald tongue. Seborrhoeic dermatitis of facial and scrotal skin characterised by fine, greasy scaling and desquamation is a common feature. Photophobia, lacrimation, burning of eyes is

also found and is believed to be due to corneal vascularisation. Personality changes have been reported rarely.

Laboratory diagnosis of riboflavin activity can be made by measurement of erythrocyte glutathione reductase activity with or without added FAD.

Treatment

Riboflavin supplementation in a dose of 5 to 10 mg per day is adequate along with improvement in the diet.

Toxicity of this vitamin has not been reported.

NIACIN (VITAMIN B_3)

Niacin refers to nicotinic acid and nicotinamide. These are converted in the body to nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), which are co-enzymes for many oxidoreductases. Therefore, these are key components of many metabolic pathways.

Dietary sources include beans, milk, meat and eggs. The RDA is 16 mg per day. The amino acid tryptophan can be converted to NAD^+ for every 60 mg of tryptophan, 1 mg equivalent of niacin is produced.

Niacin Deficiency

A diet which is poor in both niacin and tryptophan leads to niacin deficiency, e.g. diet based on maize (corn). High leucine content of *Sorghum* inhibits conversion of tryptophan to niacin. Pyridoxal phosphate acts as co-factor in synthesis of niacin from tryptophan. Thus, vitamin B_6 deficiency potentiates niacin deficiency. Alcoholism and isoniazid therapy for TB are common causes of niacin deficiency. Rare causes are carcinoid syndrome and Hartnup disease.

Clinical Features

Syndrome of niacin deficiency is known as pellagra. The manifestations include 4D's: 'dermatitis, diarrhoea, dementia and death'. The initial symptoms are irritability, loss of appetite, vomiting, abdominal pain and glossitis. The dermatitis manifests as hyperpigmented patches with scaling in sun-exposed areas. The skin rash around the neck is termed as 'Casal's necklace'. Diarrhoea occurs due to proctocolitis as well as malabsorption syndrome. Dementia, which is associated with depression and seizures, can ultimately lead to death.

Investigations done are measurement of urinary excretion of metabolites of niacin.

Treatment

Nicotinic acid or nicotinamide is given 100 to 200 mg orally three times a day for 5 days.

Other uses of nicotinic acid include treatment of dyslipidaemia where higher doses are required (>1.5 g per day).

Toxicity

The most frequent side-effect is cutaneous flushing. It improves with continuous administration or can be prevented with pre-treatment with nonsteroidal anti-inflammatory drugs (NSAIDs). The most serious adverse effect is hepatotoxicity. Few cases of fulminant hepatitis have been reported with high doses of niacin (3-6 g per day).

Niacin potentiates the action of warfarin. Other toxic effects are glucose intolerance, gastro-oesophageal reflux, and macular oedema.

PANTOTHENIC ACID

It is formed by combination of pantoic acid and alanine. It is a component of co-enzyme A (CoA). It is essential for synthesis and oxidation of fatty acids, synthesis of cholesterol, steroids and vitamins A and D. CoA is also required for formation of various amino acids and delta-ALA. Deficiency of pantothenic acid is rare because it is widely distributed in foods. Liver, egg yolk, vegetables, whole grain cereals and legumes are good sources of pantothenic acid. The RDA is 5 mg per day.

Deficiency has been reported after feeding semi-synthetic diets or by using specific antagonist of the vitamin in the diet. Symptoms are fatigue, depression, vomiting, abdominal pain, muscle cramps and paraesthesias. The burning feet syndrome, in prisoners of war during World War II, was found to be due to pantothenic acid deficiency. This syndrome is also known as Gopalan's syndrome and responds to parenteral calcium pantothenate. No toxicity of this vitamin has been reported.

PYRIDOXINE (VITAMIN B_6)

Vitamin B_6 consists of 3 closely related compounds: pyridoxine, pyridoxal and pyridoxamine, along with their corresponding phosphates. They can be interconverted in the body. Pyridoxal phosphate acts as a co-factor in amino acid metabolism and glycogenolysis. Vitamin B_6 is essential for the synthesis of haem, neurotransmitters, and synthesis of niacin from tryptophan.

Dietary sources include meat, legumes, nuts, wheat bran and eggs. The RDA is 1.5 mg per day.

Pyridoxine Deficiency

Dietary deficiency occurs along with deficiency of other B vitamins. Alcoholism, malabsorption and dialysis can cause deficiency of pyridoxine. Drugs like isoniazid, cycloserine, and penicillamine inhibit metabolism of vitamin B_6. Pregnant and lactating mothers manifest vitamin B_6 deficiency due to increased requirement.

Clinical Features

Angular stomatitis, glossitis and cheilosis are seen with deficiency of vitamin B_6. Dermatitis associated with pellagra can respond to this vitamin. Neurological defects include peripheral neuropathy, personality changes, depression, confusion and abnormal electroencephalogram (EEG). Seizures in infants are attributed to pyridoxine deficiency. Haematological manifestations include microcytic hypochromic anaemia due to diminished haemoglobin synthesis. Sideroblastic anaemia responds to pyridoxine therapy. In sideroblastic anaemia, there is failure of incorporation of iron into haem. The excess iron accumulates in the mitochondria of erythroblasts, which are called sideroblasts.

Since pyridoxine is required for metabolism of homocysteine, deficiency of pyridoxine leads to hyperhomocysteinaemia. It is believed to accelerate atherosclerosis and it is an independent risk factor for cardiovascular diseases.

Increased ratio of AST (SGOT): ALT (SGPT) found in chronic alcoholics is due to deficiency of pyridoxal phosphate, which is required for synthesis of ALT.

Treatment

Pyridoxine, given at dose of 10 to 20 mg per day, is effective for oral lesions and peripheral neuropathy. Haematological manifestations require higher doses of 50 to 200 mg per day. Also pyridoxine is used to treat Isoniazid psychosis.

Pyridoxine is given to suppress vomiting in pregnancy with 20 mg per day. Pyridoxine is also used for breast milk suppression. In hyperhomocysteinaemia pyridoxine is given along with folate and vitamin B_{12}.

Toxicity

Toxicity of pyridoxine occurs with long-term use at high doses (100-200 mg per day). It manifests as severe sensory neuropathy. Rarely, photosensitivity and dermatitis are seen.

BIOTIN

Biotin is an imidazole derivative, which acts as co-enzyme for the carboxylases. Carboxylase enzymes are involved in carbohydrate and lipid metabolism. Food sources of biotin include liver, soy, beans, yeast and egg yolk. The RDA is 30 µg per day. A large portion of the human requirement of biotin is met by intestinal bacterial synthesis. Deficiency of biotin is rare. It can be caused by ingestion of diet with large quantities of raw egg-white which contains a heat labile protein, avidin. Avidin tightly binds with biotin in gastrointestinal treat and prevents its absorption. Consumption of boiled eggs does not lead to biotin deficiency. Other causes are biotin-free total parenteral nutrition and malabsorption syndrome. Symptoms include depression, hallucination, paraesthesias, myalgia, anorexia and vomiting. Scaling, seborrhoeic, and erythematous rash may be seen on face and extremities. Infants present with hypotonia, apathy, lethargy, alopaecia and skin rash. Treatment consists of biotin supplements in doses up to 10 mg per day. No toxicity of this vitamin has been reported.

FOLIC ACID

Folic acid or folate consists of pteridine attached to PABA and glutamic acid. The active form of this vitamin is tetrahydrofolate. It is a carrier for activated one-carbon units in various metabolic reactions. Folate is required for synthesis of nucleotides, which are the building blocks of deoxyribonucleic acid (DNA), and for synthesis of methionine from homocysteine.

Green leafy vegetables and fruits are the primary sources of folate in the diet. The RDA is 0.5 mg per day. Requirements are increased in pregnancy, infants, malignancy and exfoliative skin diseases, i.e. the states with high cell turnover and increased DNA synthesis.

Aetiology—Folic Acid Deficiency

The major cause of folic acid deficiency are inadequate dietary intake, alcoholism, states of increased folate requirement, malabsorption, e.g. tropical sprue, intake of phenytoin, barbiturates. Drugs like methotrexate, trimethoprim, pyrimethamine and pentamidine impair folate metabolism.

VITAMIN B_{12}

It is an organometallic compound with corrin ring and cobalt atom at the centre. It is stored in the liver in the form of methylcobalamin and adenosylcobalamin. The commercial preparation is cyanocobalamin. Methylcobalamin is a co-enzyme in the conversion of homocysteine to methionine and of methyl-tetrahydrofolate to tetrahydrofolate. Thus, deficiency of vitamin B_{12} results in deficiency of tetrahydrofolate; which is being trapped as methyl-tetrahydrofolate. This is known as folate trap. Adenosylcobalamin is necessary for the conversion of methyl-malonyl CoA to succinyl CoA.

Animal products are the only dietary sources, i.e. meat and dairy products. It is totally absent in plant products. The RDA is 2.5 µg per day.

Aetiology—Vitamin B_{12} Deficiency

Inadequate intake occurs in vegans, i.e. strict vegetarians who do not even consume milk and milk products. Poor absorption occurs due to achlorhydria, gastrectomy, pernicious anaemia, malabsorption syndromes, ileocaecal TB, blind loop syndrome and fish tapeworm (*D. latum*) infestation.

Clinical Features of Vitamin B_{12} and Folic Acid Deficiency

Haematological effects are characterised by megaloblastic anaemia, which may be associated with leucopaenia and thrombocytopaenia. Patient presents with pallor, other features of anaemia, hyperpigmentation of skin and sometimes with icteric tinge. Peripheral smear shows macrocytes and hypersegmented neutrophils.

Neurological manifestations occur due to vitamin B_{12} deficiency. There is demyelination of peripheral nerves, posterior and lateral columns of spinal cord and brain. Patient presents with paraesthesia and numbness of extremities, weakness and sensory ataxia. Sphincter disturbances may be present. This condition is called subacute combined degeneration of spinal cord. Involvement of brain results in irritability, dementia or frank psychosis. Neurological disease may occur without haematological manifestations. Folate supplementation alone unmasks the neurological presentation of vitamin B_{12} deficiency.

Folic acid deficiency in pregnancy is responsible for neural tube defects in the foetus. Hence, folic acid supplementation is advocated in pregnant women. Plasma homocysteine levels are elevated in both folate and vitamin B_{12} deficiency. It is a risk factor for arterial and venous thrombosis. However, it is not yet clear whether folate and vitamin B_{12} supplements have favourable effects on the occurrence of cardiovascular events.

Investigations

Serum levels of vitamin B_{12} and folate are measured by radioimmunoassay. Serum methylmalonic acid and homocysteine are elevated in vitamin B_{12} deficiency and homocysteine is also elevated in folate deficiency. The pathogenesis of vitamin B_{12} deficiency can be delineated by Schilling's test.

Treatment

Oral cobalamin 1 to 2 mg per day is sufficient in patients with poor intake of the vitamin. In patients with poor absorption, cyanocobalamin is given intramuscularly at dose of 1 mg per week for 8 weeks, followed by 1 mg per month for the rest of the life. Toxicity of this vitamin has not been reported.

Folic acid is replaced at doses of 1 to 5 mg per day orally. Folate in large doses can correct the megaloblastic anaemia of

vitamin B_{12} deficiency; but neurological manifestations may be aggravated. Hence, combination therapy is preferred. Haematological abnormalities respond to therapy rapidly. The response of neurological abnormalities is slow, and may not be complete.

VITAMIN C

Ascorbic acid and dehydroascorbic acid have vitamin C activity in the body. Ascorbic acid acts as a donor of reducing equivalents, and thus, serves as a biological antioxidant. Vitamin C is essential in a multitude of biological reactions like oxidation of tyrosine in formation of norepinephrine and hydroxylation of proline in collagen synthesis. It acts as an antioxidant and prevents conversion of nitrites and amines to carcinogenic nitrosamines. Presence of vitamin C in the gastrointestinal tract significantly enhances the absorption of iron.

Dietary sources include citrus fruits, tomatoes and green vegetables. *Amla* and guava are the richest sources of vitamin C. The RDA is 60 mg per day.

Aetiology—Vitamin C Deficiency

Poor dietary intake usually occurs in the elderly and alcoholics. Smoking, haemodialysis and stress (infection, trauma) increase requirement of vitamin C.

Clinical Features

Scurvy is the classical syndrome of vitamin C deficiency. The basic defect is in the formation of mature connective tissue resulting in capillary fragility. There is bleeding into skin (petechiae, ecchymoses and perifollicular haemorrhages), inflamed and bleeding gums. There may be internal bleeding into joints, in peritoneal cavity, pericardium, adrenal glands. Wound healing is delayed and susceptibility to infections may be observed.

In children, there is impaired bone growth. The characteristic signs are tenderness of bones and follicular hyperkeratosis. Scorbutic rosary is seen due to enlargement of costochondral junctions. Typical radiological changes are detected, particularly around the knee joint.

Treatment

Administration of vitamin C 200 mg per day improves the symptoms over several days.

High doses of vitamin C (1-2 g per day) are given to shorten the duration and symptoms of upper respiratory tract infection. Diets rich in vitamin C have been claimed to reduce the incidence of oesophageal and gastric cancers. Vitamin C supplements are useful in osteogenesis imperfecta and Chediak-Higashi syndrome.

Toxicity

Very high doses of vitamin C (>2-3 g per day) can cause abdominal pain, diarrhoea, nausea and elevated ALT. It can also lead to haemolysis in G6PD deficient people, oxaluria and renal calculi. There is a risk of iron overload in the patients receiving iron supplements. Sudden withdrawal after chronic ingestion of high doses of vitamin C can lead to 'rebound scurvy'. Vitamin C interferes with laboratory tests for detection of occult blood in stool (guaiac reaction).

CONCLUSION

Water soluble vitamins are essential micronutrients. Their deficiency results in various biochemical alterations in the body which lead to the typical clinical syndromes. It is important for a clinician to recognise these, as these are easily correctable with vitamin supplements. However, considering the toxicity of some of these vitamins, the routine use of supplements in all the patients is not advisable. A balanced diet is the key to the prevention of vitamin deficiency states.

25.5 Fat Soluble Vitamins

Ghan Shyam Pangtey

INTRODUCTION

Vitamin is coined from the word vital plus amine but later it was found that amino acid is not common in most vitamins. Vitamins are mainly divided into two groups: water soluble (vitamins B-complex and C) and fat-soluble (A, D, E and K). Unlike water-soluble vitamins that need regular replacement in the body, fat-soluble vitamins can be stored for long periods in the human body in liver and fatty tissues and are eliminated much more slowly than water-soluble vitamins. The differences between the water soluble and fat soluble vitamins are summarised in **Table 1**.

Table 1: Differences between Fat Soluble Vitamin and Water Soluble Vitamin

Properties	Fat soluble vitamins	Water soluble vitamins
Major vitamin	A, D, E, K	Vitamin B complex and C
Solubility	Fat soluble	Water soluble
Absorption	Along with lipids, requires bile secretion	Simple absorption
Storage	Mainly liver and sometime fatty tissue (large amount)	Usually no storage
Excretion	Not excreted	Excreted
Deficiency	Late manifestation	Early manifestation
Toxicity	Present	Unlikely
Treatment of deficiency	Single dose may be effective	Regular dietary supplementation is required

When consumed in excess, fat-soluble vitamins can cause toxicity as they are stored for long periods, this is not true for the water soluble vitamins, as these water soluble vitamins can easily get excreted from body and thus unlikely to have high concentration leading to adverse effects. Eating a normal, well-balanced diet will not lead to toxicity in otherwise healthy individuals. However, taking vitamin supplements that contain mega doses of vitamins A, D, E and K may lead to toxicity as the body only needs small amounts of these vitamins. The recommended dietary allowance (RDA) of Indian populations has been made and revised by Indian Council of Medical Research (ICMR) in 1988 and are available for some vitamins but it is infrequently used. **Table 2** presents the United States RDA of fat soluble vitamins according to different age groups.

VITAMIN A

Vitamin A (retinol) is an essential nutrient, needed in small amounts by humans for the normal functioning of the visual system; growth and development; and maintenance of epithelial cellular integrity, immune function, and reproduction. Three different forms of vitamin A are active in the body: retinol (alcohol form), retinal (aldehyde form) and retinoic acid (acid form) which are collectively called retinoids. The retinal is the active component of vitamin A associated with visual function. The vitamin A deficiency is one of the major causes of severe visual impairment/blindness, in a recent study from India, 7.5% to 25% of blindness was reported to be due to vitamin A deficiency.

Table 2: Recommended Dietary Allowances (RDAs)/Adequate Intake of Fat Soluble Vitamins for Individuals

Life stage	Vitamin A (RAE*)	Vitamin D** (µg/d)	Vitamin E (µg/d)	Vitamin K (µg/d)
Infants	400-500	5	4-5	2-2.5
Children (1-13 yr)	300-600	5	6-11	30-60
Males (>14 yr)	900	5-15	15	75-120
Females (>14 yr)	600-700	5-15	11-15	75-90
Pregnancy	750-770	5	15	75-90
Lactation	1200-1300	5	19	75-90

*Nate: *as retinal acid equivalent. 1RAE = 1 µg retinal, 12 µg β carotene; ** As calciferol. 1 µg calciferol = 40 IU vitamin D.*

Source: Adapted fram Faad and Nutritian Baard, Institute af Medicine-Natianal Academy af Sciences: Dietary Reference Intake, 2002. National Academy Press, Washington, DC.

Vitamin A Metabolism

Food derived from animals provide compound (retinyl esters) that are easily converted in intestine to retinol. Food derived from plants provides carotenoids, some of which may have vitamin A activity. There are more than 600 carotenoids in nature; β carotene is the most prevalent carotenoid with vitamin A activity, which can be split into intestine and liver to retinol. The β carotene absorption and conversion is less efficient than retinoids. The 12 µg of β carotene is equivalent to 1 µg of retinol.

The retinol binding protein (RBP) is the special transport protein which binds to retinol in blood and transports it to the appropriate cells that have specific protein receptors for their binding.

Vitamin A Biological Role

The major role of vitamin A in body includes:

- Supporting growth and reproduction
- Promoting vision
- Maintenance and growth of epithelial cells of skin and mucous membrane
- Antioxidant.

The vitamin A retinol has the major role in transport of vitamin A and in supporting growth and reproduction. In men retinol participates in sperm development and in women it supports normal foetal development. Retinol also has major role in the normal growth and remodelling of bones. The retinal plays two major roles in normal vision. Firstly, it is required for maintenance of crystal clarity of cornea and secondly it participates in the conversion of light energy into nerve impulse in the retina. The rhodopsin pigment present in retina

is composed of a molecule of retinal and a protein opsin. When light strikes the retina the rhodopsin pigment gets bleached and retinal shifts from *cis* to *trans* configuration. This *trans* retinal cannot bind to opsin leading to change in membrane potential of opsin and activation of electrical impulse, which transmits it to nerve cell and later to brain. Much of *trans* retinal is converted back to active *cis* form but small amount of it gets converted to irreversible retinoic acid which has to be replaced with dietary intake.

Retinoic acid-vitamin A has important role in promotion of cell differentiation and protein synthesis leading to normal development of epithelial cells of skin and mucous membrane integrity.

Sources of Vitamin A

The vitamin A recommendations are expressed in retinol activity equivalent (RAE). One RAE equals to1 µg of retinol; 12 µg of β carotene; 3.33 IU of vitamin A. Previously the vitamin A recommendations were used to be given in international units (IUs) but it is now expressed in µg and the same will be used in this chapter. **Table 2** summarises the estimated mean requirements for vitamin A and the recommended safe intakes, taking into account the age and sex differences in mean body weights.

Preformed vitamin A is found almost exclusively in animal products, such as human milk, glandular meats, liver and fish liver oils, egg yolk, whole milk, and other dairy products. Preformed vitamin A is also used to fortify processed foods, which may include sugar, cereals, condiments, fats and oils. Provitamin A carotenoids are found in green leafy vegetables (e.g. spinach, amaranth and young leaves from various sources), yellow vegetables (e.g. pumpkins, squash, and carrots), and yellow and orange non-citrus fruits (e.g. mangoes, papayas).

Foods containing pro-vitamin A carotenoids tend to have less biologically available vitamin A but are more affordable than animal products. It is mainly for this reason that carotenoids provide most of the vitamin A activity in the diets of economically deprived populations.

Vitamin A Deficiency (VAD)

Vitamin A deficiency is a major health problem of developing countries. World Health Organisation (WHO) estimates that more than 100 million children's have some degree of deficiency. In a recent study from India, the prevalence of Bitot's spots and night blindness in schoolchildren was found to be around 5%, while prevalence of night blindness in pregnant females was found to be as high as 20% in few centres. The ocular manifestation due to VAD is known as xerophthalmia. The night blindness is the earliest manifestation of the VAD in which there is lack of vitamin A in back of eye (retina), in later stages of xerophthalmia there may be total blindness due to involvement of front of eye (cornea). The corneal involvement starts with dryness and hardening (xerosis) and later followed by softening, ulceration and necrosis (keratomalacia).

The normal range of serum vitamin A (retinol) is between 30-100 µg/dL. The other methods used to diagnose normal levels are blood spot retinol, tests for dark adaptation and liver biopsy to estimate the vitamin A reservoir. The serum level below 20 µg/dL is regarded as VAD. The clinical and subclinical infections can lower serum levels of vitamin A, on an average by as much as 25%, independently of vitamin A intake.

Management of Vitamin A Deficiency

Any stage of xerophthalmia should be treated with three 60 mg of vitamin A soft gel capsule given on day 0, day 1 and day 14. The dose should be half (30 µg) for the children's in the age group of 6 to 11 months. Pregnant mothers with deficiency should be a treated with 7.5 mg per week for 3 months. Patients with malabsorption should be treated with 15 mg per day of water soluble vitamin A and this should be followed by maintenance dose according to serum retinol levels.

Prophylactic vitamin A dose of 60 mg every 6 months is recommended in high-risk individuals and similarly children's suffering from measles should be given two capsules of 60 mg for two consecutive days.

Vitamin A Toxicity

Routine consumption of large amounts of vitamin A over a period of time can result in toxic symptoms, including liver damage, bone abnormalities and joint pain, alopecia, headaches, vomiting and skin desquamation. Hypervitaminosis A appears to be due to abnormal transport and distribution of vitamin A and retinoids caused by overloading of the plasma transport mechanisms. Very high single dose can also cause transient acute toxic symptoms that may include bulging fontanelles in infants; headaches in older children and adults; and vomiting, diarrhoea, loss of appetite and irritability in all age groups.

VITAMIN D

Vitamin D (calciferol) is the only vitamin which can be synthesised in human body. It is required to maintain normal blood levels of calcium and phosphate, which are in turn needed for the normal mineralisation of bone, muscle contraction, nerve conduction, and general cellular function in all cells of the body. Vitamin D achieves this after its conversion to the active form 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], or calcitriol. This active form regulates the transcription of a number of vitamin D-dependent genes which code for calcium-transporting proteins and bone matrix proteins.

Metabolism of Vitamin D

Vitamin D, a seco-steroid, can either be made in the skin from the cholesterol like precursor (7-dehydrocholesterol) by exposure to sunlight or can be provided pre-formed in the diet. The version made in the skin is referred to as vitamin D_3 or cholecalciferol whereas the dietary form known as vitamin D_2 or ergocalciferol (**Figure 1**). The vitamin D is also known as a prohormone because it can be synthesised in human body and acts like a hormone at distant target cells.

The vitamin D_3 is metabolised first in the liver to 25-hydroxyvitamin D (calcidiol) and subsequently in the kidneys to1,25$(OH)_2$D (calcitriol) to produce a biologically active hormone. The calcitriol and other vitamin D metabolites are complexed to vitamin D-binding protein (globulin) in the blood. Calcitriol is believed to act on intracellular receptors similar to steroid hormones.

Recently there has been rising interest in the discovery of vitamin D receptors in more than 20 different cells of the body

which includes brain, bone marrow cells, skin, lymphocytes, etc. The exact role of these receptors is still unknown but it is speculated that this may have some important functions of immunomodulation and cell differentiation.

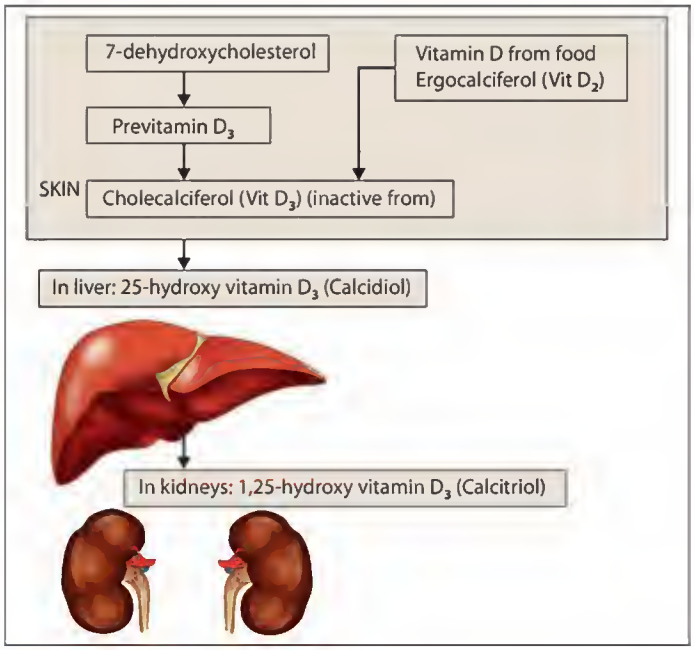

Figure 1: Synthesis of vitamin D in humans.

Sources of Vitamin D

The most efficient and physiologically relevant endogenous synthesis of vitamin D is from the skin. This is maximum in the world, in a broad band around the equator. Approximately 30 minutes of adequate exposure of arms and face to sunlight can provide the daily adequate requirement of an individual. However, skin synthesis of vitamin D is negatively influenced by the following factors: latitudes >42° N or >42° S, winter months, thinned skin of elderly, dark pigmented skin (Asian and Africans), clothing and sunscreens use. It is reported that in winter months, persons living in latitudes higher than 42° have zero vitamin D synthesis.

Vitamin D recommendation is usually given in international unit (IU) and the conversion used is 1IU = 0.025 µg cholecalciferol. The RDA for vitamin D is given in Table 2. The food sources rich in vitamin D are fortified dairy products, fortified margarine, fish oils and egg yolk.

Vitamin D Deficiency

Vitamin D deficiencies is widely prevalent in India and in recent studies up to 90% of Indians are found to be having hypovitaminosis D, which may be due to dark skin complexion, poor sun exposure, vegetarian food habits and lack of vitamin D in food fortification programme. The vitamin D acts on intestinal cells to increase calcium absorption from gut, therefore, in its deficiency serum ionised calcium level decreases leading to rickets in children's and osteomalacia in adults. Optimal vitamin D level of 25(OH) D is >25 ng/mL (37 nmoL/L) but the level at which the parathyroid hormone (PTH) increases and bone density decreases is <15 ng/mL of vitamin D.

Management of Vitamin D Deficiency

Recommended daily intake of 800 IU of vitamin D is associated with decrease in risk of hip fracture in elderly. The cause of vitamin D deficiency should be investigated and treated first before vitamin D and calcium correction. In patient with chronic renal insufficiency or 1α-hydroxylation defect the treatment should be with 0.25-0.5 µg/day of calcitriol [1, $25(OH)_2D_3$]. Patients with intact vitamin D hydroxylation should be treated with 60,000 IU of cholecalciferol sachet/week for 4 to 12 weeks followed by maintenance therapy of once monthly sachet or 800 IU daily. In patients with fat malabsorption intramuscular vitamin D should be used in the dose of 2.4 lac IU/6 months.

Vitamin D Toxicity

The safety margin of vitamin D is very large and the toxicity is only seen at very large doses in the range of 40,000 IU/day. It may lead to hypercalcaemia and hypercalciuria, leading to nephrolithiasis if urinary calcium rises >250 mg/24 hour.

VITAMIN E

Vitamin E consists of family of eight naturally occurring isomers of tocopherol and tocotrienols that are synthesised by plant homogentisic acid. It is the major lipid-soluble antioxidant in the cell antioxidant defence system and is exclusively obtained from the diet. The major biological role of vitamin E is to protect polyunsaturated fatty acids (PUFAs) and other components of cell membranes and low-density lipoprotein (LDL) from oxidation by free radicals. The recent studies do not document the beneficial role of vitamin E as antioxidant to prevent heart disease and cancer as previously thought.

Vitamin E Metabolism

Absorption of vitamin E from the intestine depends on adequate pancreatic function, biliary secretion and micelle formation. Conditions for absorption are like those for dietary lipid, that is, efficient emulsification, solubilisation within mixed bile salt micelles, uptake by enterocytes, and secretion into the circulation via the lymphatic system. After absorption of tocopherol (vitamin E), it is incorporated into the chylomicrons in the enterocyte and secreted into the lymphatic's and blood stream. The chylomicrons carry tocopherols to the liver parenchymal cells as well as in systemic circulations where they are acted upon by lipoprotein lipase and get incorporated inside the very low-density lipoprotein (VLDL) and LDL. The tocopherol is mainly delivered to the peripheral tissue by the LDL through LDL receptor mechanism.

Dietary Sources of Vitamin E

Vitamin E is naturally present in plant based diets and animal products. The vegetable oils and their products are the major source (60%) of vitamin E in human diet. The other important sources of vitamin E are animal fats, vegetables, meats, fruits, nuts, cereals and dairy products. Small amount of vitamin E is also present in eggs, fish, and pulses. The RDA for vitamin A is 15 mg per day for all adults.

Vitamin E Deficiency

The dietary deficiency of vitamin E usually does not exist. This suggests that diets contain sufficient vitamin E to cover nutritional needs. The deficiency in humans is usually seen in infants and adults with fat-malabsorption syndromes or liver disease, in individuals with genetic anomalies in transport or binding proteins (e.g. abetalipoproteinaemia), and possibly in premature infants. The deficiency may precipitate in the

community at times of ecological disaster and famine. Disorders provoked with low vitamin E status include cardiac or skeletal myopathies, neuropathies, and liver necrosis. The blood levels of α tocopherol <5 μg/mL is suggestive of vitamin E deficiency.

Management of Vitamin E Deficiency

In deficient states vitamin E is required to be given in doses of 800-1200 mg per day. In patients with abetalipoproteinaemia the dose recommended is 5000-7000 mg per day of α tocopherol. In children with fat malabsorption the vitamin E deficiency should be treated with water soluble form of α tocopherol as well as by intramuscular injections.

Vitamin E Toxicity

Vitamin E appears to have very low toxicity potential, evidence of pro-oxidant damage has been associated with the feeding of supplements but usually only at very high-doses of >1000 mg per day. High-doses can also interfere with platelet aggregation and vitamin K metabolism leading to bleeding tendency. Other common symptoms of toxicity include nausea, vomiting and flatulence.

VITAMIN K

Vitamin K has essential role in maintenance of normal blood coagulation in the human body by acting as a cofactor in post-translational modification of vitamin K dependent proteins or G1a proteins. The vitamin K dependent coagulation proteins are synthesised in the liver and comprises of factors II, VII, IX, and X, which have a haemostatic role and protein C and S, which have an anticoagulant role. Nutritional deficiency of vitamin K leads to bleeding tendency.

Vitamin K Biological Role

There are two types of naturally occurring vitamin K, the phylloquinone (vitamin K_1) is synthesised by plants and menaquinone (vitamin K_2) is synthesised by bacteria. Vitamin K_1 can be converted to Vitamin K_2 in some specific organs.

The biological role of vitamin K is to act as a co-factor for a specific carboxylation reaction that transforms selective glutamate (Glu) residues to α-carboxyglutamate (Gla) residues.

Apart from the coagulation proteins, several other vitamin K-dependent proteins have been isolated from bone, cartilage, kidney, lungs, and other tissues. Only two, osteocalcin and matrix Gla protein (MGP), have been well characterised. Both are found in bone but MGP also occurs in cartilage, blood vessel walls, and other soft tissues. Evidence of a possible association of a suboptimal vitamin K status with increased fracture risk remains to be confirmed.

Sources of Vitamin K

The highest values of phylloquinone (normally in the range 400-700 mg/100 g) are found in green leafy vegetables (turnip greens, spinach, cauliflower, cabbage and broccoli, etc.). The next best sources are certain vegetable oils (e.g. soyabean, rapeseed, and olive), which contain 50-200 mg/100 g. The animal food is generally poor source of vitamin K. The average daily requirement in adult is 100 μg per day.

Animals and humans obtain a significant fraction of their vitamin K requirement from direct absorption of menaquinones produced by bacterial microflora present in the gut.

Vitamin K Deficiency

Infants up to around age of six months are prone to vitamin K deficiency due to low levels of vitamin K in breast milk, low fat store, gut sterility, liver immaturity and poor placental transfer of vitamin K. The deficiency syndrome has been termed vitamin K deficiency bleeding (VKDB) disorder.

In adults, primary vitamin K-deficient states that manifest as bleeding are almost unknown except when the absorption of the vitamin K is impaired as a result of an underlying chronic small intestinal disease (e.g. coeliac sprue) or intestinal resections.

Diagnosis of vitamin K deficiency can be made by direct measurement or by prolonged prothrombin time.

Management of Vitamin K Deficiency

Vitamin K deficiency should be treated with 10 mg of parentral dose. In chronic malabsorption states the vitamin K dose required is 1-2 mg per day orally or 1-2 mg per week parentrally.

Vitamin K Toxicity

When taken orally, natural K vitamins seem free of toxic side-effects. However, synthetic preparations of menadione or its salts may be associated with neonatal haemolysis and liver damage. High-doses of vitamin K can impair the actions of oral anticoagulants.

25.6 Minerals, Trace Elements and Antioxidants

M Raghunath, D Sreeramulu

MINERALS

Although minerals constitute small proportion of the human body, they perform several vital functions which are absolutely essential for normal metabolism. Most of the minerals are provided by the diet one consumes. Minerals are classified as major elements and trace elements according to the quantities present in the body and required by humans. If more than 100 milligrams (mg) of an element is needed per day, it is classified as major mineral and the minerals which are present and needed in amounts less than 100 mg per day are classified as trace elements. They are subdivided as follows in Table 1.

Table 1: Minerals and Trace Elements

Major Minerals	Trace Elements		
	Essential	**Possibly essential**	**Non-essential (to date)**
Calcium (Ca)	Iron (Fe)	Cadmium (Cd)	Aluminum (Al)
Phosphorus (P)	Iodine (I)	Barium (Ba)	Bismuth (Bi)
Sodium (Na)	Zinc (Zn)	Nickel (Ni)	Boron (B)
Potassium (K)	Selenium (Se)	Vanadium (V)	Lead (Pb)
Magnesium (Mg)	Copper (Cu)	—	Mercury (Hg)
Chloride (Cl)	Fluorine (F)	—	Silver (Ag)
Sulphur (S)	Molybdenum (Mo)	—	—
—	Chromium (Cr)	—	—

Calcium

Among different minerals calcium occurs in the highest amounts in the human body. About 99% of the calcium in the body is found in bones and teeth, while 1% is found in the blood and soft tissue. Calcium levels in blood and fluid surrounding the cells (extracellular fluid) must be maintained within a very narrow concentration range 9 to 11 mg/dL for normal physiological functions. Oxalic acid, also known as oxalate, is the most potent inhibitor of calcium absorption and is found in high concentrations in spinach and in lower concentrations in sweet potatoes and dried beans.

Metabolic functions of calcium

1. Calcium is essential for the formation of bones and teeth. The mineral component of bone consists mainly of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] crystals, which contain large amounts of calcium and phosphate.
2. Calcium plays a role in mediating the constriction and relaxation of blood vessels (vasoconstriction and vasodilatation), nerve impulse transmission, muscle contraction and secretion of hormones like insulin.
3. Calcium is essential for clotting of blood. It acts as a cofactor for enzymes and proteins.

Parathyroid hormone regulates calcium levels in blood and calcium metabolism in the bone. Causes of abnormal low blood calcium levels include chronic kidney failure, vitamin D deficiency and low blood magnesium levels that occur mainly in cases of severe alcoholism in addition to low dietary Ca intake.

Phosphorus

About 80% of phosphorus present in the body is in bone and teeth and 10% in muscles. Phosphate is mainly an intracellular ion and is present in all cells. Requirement of phosphorus is about 500 mg/day. Serum phosphorus levels range from 3 to 4 mg/dL in normal adults and 5 to 6 mg/dL in children and they are regulated through urinary excretion. Serum phosphorus levels are decreased in hyperparathyroidism and rickets.

Metabolic functions of phosphorus

1. Phosphorus is necessary for the formation of bone and teeth.
2. It is needed for the synthesis of nucleoside co-enzymes such as NAD and NADP, high energy phosphate compounds such as ATP, CTP, GTP, creatine phosphate and for DNA and RNA synthesis.
3. It is essential for carbohydrate and lipid metabolism, e.g. formation of phosphate esters such as glucose 6-phosphate and phospholipids.
4. Activation/inactivation of enzymes occur by phosphorylation/dephosphorylation.
5. To maintain the phosphate buffer system in blood, the ratio of Na_2HPO_4: NaH_2PO_4 required in blood is 4:1 and this responsible to maintain pH of blood at 7.4.

Sodium

About 50% of sodium present in the body is in bones, 40% in extracellular fluid (ECF) and about 10% in soft tissues. Normal plasma sodium levels range from 136 to 145 mEq/L. It is a major cation which regulates extracellular fluid volume. Sodium pump operates in all cells to maintain sodium extracellular in an ATP dependent mechanism.

Metabolic functions of sodium

1. The Na^+-K^+ ATPase pump moves three sodium ions out of the cell in exchange for two potassium ions moving into the cell during which process ATP is hydrolysed to ADP.
2. Sodium ions play a special role in originating and maintaining the heartbeat and transmission of nerve impulse.

Potassium

About 75% of body potassium is present in skeletal muscle. Normal levels of plasma potassium ranges from 3.5-5 mEq/L. It is one of the major intracellular cation, and it helps to maintain the intracellular osmotic pressure.

Metabolic functions of potassium

1. Potassium helps to maintain intracellular pH and osmotic pressure.

2. Required for contraction of heart and transmission of nerve impulses.

Magnesium

Magnesium plays an important role in the structure and function of the human body. The adult human body contains about 25 grams of magnesium. Over 60% of all the magnesium in the body is found in the skeleton, about 27% in muscle, 6% to 7% in other cells and less than 1% is found outside the cells. Because magnesium is a part of chlorophyll, the green pigment in plants, green leafy vegetables are rich in magnesium. Magnesium is involved in more than 300 essential metabolic reactions.

Metabolic functions of magnesium

1. The metabolism of carbohydrates and fats to produce energy requires numerous magnesium-dependent chemical reactions; such as the adenosine triphosphate (ATP).
2. Magnesium plays a structural role in bone, cell membranes and chromosomes. It is necessary for proper calcium and vitamin D metabolism.
3. Magnesium affects the conduction of nerve impulses, muscle contraction and normal heart rhythm through the active transport of ions like potassium and calcium across cell membranes.
4. Mg is required in cell signalling for the phosphorylation of proteins and formation of cyclic adenosine monophosphate (cAMP). It is also involved in cell migration and helps in wound healing.

Magnesium deficiency is quite rare in healthy individuals who consume balanced diet since magnesium is abundant in both plant and animal foods. However, in some disease conditions like gastrointestinal, renal disorders and chronic alcoholism, etc. the risk of magnesium deficiency is increased. Mg deficiency leads to hypertension, cardiovascular disease, endothelial dysfunction, diabetes mellitus, osteoporosis and asthma.

Chloride

Chloride concentrations in plasma range from 96 to 106 mEq/L. The homeostasis of Na, K and Cl are interrelated. Chloride is important in the formation of hydrochloric acid in gastric juice. Chloride is excreted through urine and sweat. Renal threshold is about 110 mEq/L. Daily excretion of Cl^- is about 5 to 8 g per day.

Metabolic functions of chloride

Chloride is the major extracellular anion. It is involved in maintaining osmolality, blood volume, and electric neutrality.

Sulphur

Sulphur present in the body in the form of sulphur-containing amino acids cysteine and methionine in the body proteins. Hence, the source of sulphur is mainly from the amino acids: cysteine and methionine. Proteins contains about 1% sulphur by weight. Inorganic sulphates of Na^+, K^+ and Mg^{++} though available in food are not utilised by the body. All sulphur groups are ultimately oxidised in liver to sulphate (sulphuric acid) group and excreted in urine. The total quantity of sulphur in urine is about 1 g per day.

Metabolic functions of sulphur

1. Sulphur containing amino acids are important constituents of body proteins. The di-sulphide bridges keep polypeptide units together, e.g. insulin, immunoglobulin's, etc.
2. Keratin, rich in sulphur, is present in hair and nails.
3. Sulphates play an important role in detoxification mechanisms.

The major food sources of the minerals, their deficiency, symptoms and recommended daily allowances (RDAs) are given in **Table 2**.

TRACE ELEMENTS

Iron

Iron has the longest and best described history among all the micronutrients. It is a key element in the metabolism of almost all living organisms. In humans, iron is an essential component of hundreds of proteins and enzymes. Most of the body iron exists in complex forms bound to protein either as porphyrin or haemcompounds or as ferritin and transferrin. Iron is required for the formation of haemoglobin in RBC and is involved in oxygen transport and storage. Copper is essential for utilisation of iron for haemoglobin formation. Iron depletion leads to iron deficiency anaemia. About 50% to 60% of Indian population suffers from iron deficiency anaemia. Iron is absorbed only in the ferrous form. The dietary iron absorption in normal individuals is only around 10% of intake.

Table 2: Summary of Major Minerals (Food Sources, Effect of Deficiency and RDA)

S. No.	Mineral	Major Food Source	Deficiency Symptoms	RDA
1.	Calcium	Milk, milk products, GLVs, dried small fish	Decreased growth, osteoporosis and hyperplasia	300 to 500 mg
2.	Phosphorus	Milk, egg, meat and fish	Hyperthyroidism and rickets	500 mg
3.	Sodium	Milk and pulses	Heat cramps and headache	200 to 500 mg
4.	Potassium	Banana, oranges, apple, pineapple and tender coconut water	Weakness, muscular paralysis	3 to 4 g
5.	Magnesium	Cereals, pulses, coffee, tea	Neuromuscular hyperirritability cardiac arrhythmias and symptoms are similar to calcium deficiency	200 to 300 mg
6.	Chloride	Egg, pulses, whole and skim milk	Excess sweating and vomiting, Addison's disease	300 to 750 mg
7.	Sulphur	Amino acid cysteine and methionine	Obstructive jaundice, amino-aciduriase Taurocholic acid in urine	850 mg

Metabolic role of iron

1. Haemoglobin is the primary protein in red blood cells and represents about two thirds of the body iron.
2. Iron participates in electron transport and energy metabolism and DNA synthesis and plays a role in antioxidant functions.

Iodine

Iodine is a constituent of thyroxin, the active principle of the thyroid gland. It is a non-metallic trace element, required for the synthesis of thyroid hormone in humans. Iodine deficiency is an important health problem throughout much of the world. Iodine deficiency is now accepted as the most common cause of preventable brain damage in the world. According to the World Health Organisation (WHO), iodine deficiency disorders (IDD) affect 740 millions people throughout the world and nearly 50 millions people suffer from some degree of IDD. The spectrum of IDD includes mental retardation, hypothyroidism, goitre and varying degrees of other growth and developmental abnormalities. Thyroid enlargement or goitre is one of the earliest and most visible signs of iodine deficiency. The thyroid enlarges in response to persistent stimulation by TSH. In mild iodine deficiency, this adaptive response may be enough to provide the body with sufficient thyroid hormone. However, more severe cases of iodine deficiency result in hypothyroidism. Adequate iodine intakes reduce the size of goitres, but the reversibility of the effects of hypothyroidism depends on an individual's stage of development. Iodine deficiency has adverse effects in all stages of development but is most damaging to the developing brain. Thyroid hormones regulate a number of physiological processes including growth, development, metabolism and reproductive function.

Zinc

Zinc is an essential trace element for all forms of life. Zinc plays important roles in growth, development, immune response, neurological functions and reproduction. Approximately 300 different enzymes depend on zinc for their ability to catalyse vital chemical reactions. Zinc-dependent enzymes can be found in all known classes of enzymes. Zinc plays an important role in the structure of proteins and cell membranes. Loss of zinc from biological membranes increases their susceptibility to oxidative damage and impairs their function.

Clinical zinc deficiency in humans was first described in 1961, when the consumption of diets with low zinc bioavailability due to high phytic acid content was associated with 'adolescent nutritional dwarfism' in the Middle East. Zinc bioavailability is relatively high in meat, eggs and seafood because of the absence of compounds that inhibit zinc absorption and presence of certain amino acids (cysteine and methionine) that improve zinc absorption.

Severe zinc deficiency results in the slowing or cessation of growth and development, delayed sexual maturation, characteristic skin rashes, chronic and severe diarrhoea, immune system deficiencies, impaired wound healing, diminished appetite, impaired taste sensation, night blindness, swelling and clouding of the corneas and behavioural disturbances.

Selenium

Selenium is a component of several enzymes. It protects cell membranes, prevents free radical generation and functions as an antioxidant. There by it decreases the risk of CVDs and few cancers. Selenium is required for normal function of several selenium-dependent enzymes, also known as selenoproteins, e.g. glutathione peroxidases. It is also needed for normal maturation of spermatozoa.

Role of selenium

1. Some of the selenoproteins that are involved in the metabolism are glutathione peroxidases, thioredoxin reductase, iodothyronine deiodinases.
2. It functions as an antioxidant that protects endothelial cells from damage.
3. It is necessary for normal development of spermatozoa.

Copper

Copper (Cu) is an essential trace element for the formation of haemoglobin in the body. Copper shifts between the cuprous (Cu^{1+}) and cupric (Cu^{2+}) forms, though the majority of the body's copper is in the Cu^{2+} form. The ability of copper to easily accept and donate electrons explains its important role in oxidation-reduction (redox) reactions and in scavenging free radicals.

Role of copper

1. Copper is a critical functional component of a number of essential enzymes known as cuproenzymes. These enzymes play important roles in cellular energy production, cross-linking of collagen and elastin, iron transport and in the function of the brain and nervous system.
2. The copper-dependent enzyme, cytochrome *c* oxidase, plays a critical role in cellular energy production.

Copper deficiency may result in abnormally low numbers of white blood cells known as neutrophils (neutropaenia), a condition that may be accompanied by increased susceptibility to infections. Osteoporosis and other abnormalities of bone development are related to copper deficiency and are most common in copper-deficient low-birth weight infants and young children. Less common features of copper deficiency may include loss of pigmentation, neurological symptoms and impaired growth.

Fluorine

Fluorine occurs naturally as the negatively charged ion, fluoride (F^-). Fluoride is considered a trace element because only small amounts are present in the body and because the daily requirement for maintaining dental health is only 1 to 2 ppm. About 95% of the total body fluoride is found in bones and teeth. Although its role in the prevention of dental caries (tooth decay) is well established, fluoride is not generally considered an essential trace element because excess fluorine content in water (>2 ppm) is a major public health problem than the fluoride deficiency. About 25 million Indians spread in 15 states of India are suffering from flurosis. Among them Nalgonda, Nellore and Prakasam districts of Andhra Pradesh and Patiala district of Punjab are badly affected.

In humans, the only clear effect of inadequate fluoride intake is an increased risk of dental caries (tooth decay) for individuals of all ages. The incidence of dental caries in children is observed to be high in areas where the fluoride content of drinking water is less than 0.5 ppm. Fluoride toxicity is

observed where the drinking water contains excessive amounts of fluoride (>3 ppm). This leads to osteoporosis and osteosclerosis with brittle bones, the condition being called fluorosis, which is more dangerous than dental caries. In these cases hypercalcification of the bone of the spine, pelvis and limbs occurs. In addition, the ligaments of spine become calcified, producing a 'poker back'. Neurological disturbances were observed secondary to changes in the vertebral column. Such persons are crippled and cannot perform simple daily tasks, such as bending, squatting, etc. as the joints become stiff. Fluoride toxicity can be prevented only by removing fluorides from drinking water supplies by treatment with activated carbon or by some other suitable adsorbents.

Molybdenum

Molybdenum is one of the essential trace elements.

Molybdenum functions as co-factor for some enzymes in humans, any disturbance of molybdenum co-factor metabolism can disrupt the function of all molybdoenzymes. These disorders result from recessive traits, for those individuals who inherit two copies of the abnormal gene (one from each parent) develop the disease. The symptoms of isolated sulfite oxidase deficiency and molybdenum co-factor deficiency are identical and usually include severe brain damage, which appears due to the loss of sulfite oxidase activity. Normally the average diets provide adequate amounts of molybdenum to humans and deficiency is rare.

The major food sources of the trace elements, their deficiency symptoms and recommended daily allowances are given in **Table 3**.

Table 3: Summary of Trace Elements (Food Sources, Effect of Deficiency and RDA)

S. No.	Trace element	Major food source	Deficiency symptoms	RDA
1.	Iron	Green leafy vegetables, pulses, jaggery, poultry, fish and egg yolks	Iron deficiency anaemia, impairment of learning in children and in adults impairment of work capacity	20 to 40 mg
2.	Iodine	Shell fish, sea weeds and sea fish	Goitre, Mental retardation	150 to 200 µg
3.	Zinc	Whole grains and sea food	Growth retardation, Delayed genital maturation	10 to 15 mg
4.	Selenium	Whole grains	Muscle weakness and fatigue	50 to 100 µg
5.	Copper	Shell fish, nuts and legumes	High blood pressure fragile bones	1 to 1.4 mg
6.	Molybdenum	Legumes, grains and nuts	Amino acid intolerance and reduced fertility	75 to 250 µg
7.	Fluoride	Water, sea foods and tea	Dental caries, skeletal fluorosis	1 ppm
8.	Cobalt	Curd/milk, Dietary Source of vit B_{12}	Wasting disease observed in animals	*No RDA necessary*

ANTIOXIDANTS FREE RADICALS

Production and Physiological Relevance

Electrons are normally present in pairs. In the course of metabolism several atoms or groups of atoms are generated in the body, which have unpaired electrons, which are called free radicals. They usually seek electrons from other atoms to become paired electrons and thus stabilise their structure. Free radicals can react with proteins, nucleic acids, lipids and other molecules and alter their structure. In turn they attack other molecules due to their powerful oxidative nature and results in tissue damage. An imbalance between free radical generation and radical scavenging systems in the living organism causes oxidative stress which ends up in generation of reactive oxygen species (ROS) and RNS. It has been implicated in tissue damage, damage of lipids, proteins and DNA resulting in cell injury. Excess free radical production underlies the pathogenesis of diseases like atherosclerosis, carcinogenesis, diabetes, cataract and accelerated ageing.

Types of Free Radicals

Superoxide	O_2^-
Hydrogen peroxide	H_2O_2
Hydroxy radical	HO
Nitric oxide	NO
Lipid radicals	L
Lipidperoxyl radicals	LO2
Thiyl radicals	RS
Protein radicals	P

Sources of Free Radical

Oxidative damage can be brought about by free radicals generated from endogenous as well as exogenous sources. Some common endogenous sources are: 1. Mitochondria, 2. Electron transport, 3. Defense-phagocytes, 4. Membrane oxidases, and 5. Catecholamines.

The exogenous sources of free radicals are: 1. Alcohol, 2. Chemicals, carcinogens, 3. Pollutants, 4. Radiation, 5. Smoking (tobacco), and 6. Stress.

$$3H_2O \xrightarrow{\text{Radiation}} H_2 + H^+ + OH^- + H_2O_2$$

Physiological Relevance of Free Radicals

If the free radical production in our body is specially uncontrolled as happens under the conditions of alcoholism, over eating and smoking, the ROS/free radicals damage many of our biological systems.

Age related diseases are believed mainly to be the after effects of free radicals. In aged people the defects in secretary glands, eye sight and memory are partly due to the onslaught of free radicals and partly due to metabolic defects/nutrition, etc.

ANTIOXIDANTS

To defend against damage from free radicals and ROS, humans and other living organisms have developed powerful and complex antioxidant system. Antioxidants are diverse group of molecules that protect key biological sites from oxidative damage. They are either produced in the body (endogenous) or derived from the diet (exogenous). The endogenous antioxidant defense systems of the body are essentially of two types: enzymatic and non-enzymatic.

Different Types of Antioxidant Systems

The living organisms are endowed with a battery of antioxidant systems which defend the organism against oxidative stress due to various endogenous and exogenous sources. The balance between oxidative stress/antioxidant defense systems of the body, determine to a great extent the susceptibility of the organism to free radical/ROS induced tissue damage and associated diseases. Biological antioxidant is 'any substance that when present at low concentrations compared to those of an oxidisable substrate significantly delays or prevents the oxidation of that substrate'.

The following are the various defense systems *in vivo* against oxidative damage.

Enzymatic antioxidants

Superoxide dismutase (CuZnSOD present in Cytosol, Mn SOD in mitochondria and SOD in extracellular space), Catalase, Glutathione peroxidase (GSHPx), Glutathione reductase, etc. are the common antioxidant enzymes in the body. These are preventive antioxidants which suppress free radical formation as follows:

1. Non-radical decomposition of hydroperoxides and H_2O_2

S. No.	Antioxidant	Mechanism
i.	Catalase	Decomposition of H_2O_2
ii.	Glutathione peroxidase (cellular)	Decomposition of H_2O_2 and Free fatty acid hydroperoxides
iii.	Glutathione peroxidase (Plasma)	Decomposition of H_2O_2 and phospholipid hydroperoxides
iv.	Phospholipid hydroperoxides Glutathione peroxidase	Decomposition of phospholipids and hydroperoxides
v.	Peroxidase	Decomposition of H_2O_2 and lipid peroxides
vi.	Glutathione S transferase	Decomposes lipid hydroperoxides

2. Antioxidants that sequester metals by chelation

S.No.	Metal Chelaters	Mechanism
i.	Transferrin, Lactoferrin	Sequestration of iron
ii.	Heptoglobin	Sequestration of haemoglobin
iii.	Hemopexin	Stabilisation of haem
iv.	Ceruloplasmin, albumin	Stabilisation of copper

3. Antioxidants that quench active oxygen species: Superoxide dismutase-dismutates superoxides where as carotenoids, vitamin E, etc. Quenches singlet oxygen.
4. *De novo* enzymes: These enzymes repair the damage and reconstitute membranes, e.g. Lipase, protease, DNA repair enzymes and transferases.
5. Adaptation enzymes: These enzymes are generated at appropriate antioxidant enzymes and transfer them to the right site at the right time in right concentration.

Non-enzymatic antioxidants

Ascorbic acid, β-carotene, α-tocopherol, glutathione, selenium, lycopene, uric acid, bilirubin, flavonoids and other chemical antioxidants, etc. constitute some of the non-enzymatic antioxidants. These are radical scavenging antioxidants which scavenge radicals to inhibit chain initiation and break chain propagation, e.g. Hydrophilic ones among them are vitamin C, Uric acid, bilirubin and albumin, etc. whereas vitamin E, Ubiquinol, carotenoids and flovonoids constitute lipophylic antioxidants.

Phenolic antioxidants

These are another group of antioxidants commonly present in plant foods. A large number of phytochemicals exert antioxidant activity and are known as non-nutritional antioxidants. These natural antioxidants are present mostly in plant foods as polyphenolic compounds (Phenolic compounds made up of multiple phenol rings). These phenols, especially those with multiple phenolic groups, are found to be better antioxidants than the well-known antioxidant vitamins. There are more than 5,000 individual phenolic compounds (flavonoids, monophenols and polyphenols) identified till date and more are expected to exist in nature. Major classes of phytochemicals are given in **Table 4**.

Table 4: Major Classes of Phytochemicals with Antioxidant Activity

S. No.	Major Classes of Phytochemicals	Compounds
1.	Carotenoids	Lycopene, lutein, astaxanthin
2.	Bioflavonoids	Genistein, diadzein, quercetin
3.	Phytosterols	Sitosterol, Stigmasterol, oryzanol
4.	Tannins	Catechins and other polyphenol compounds
5.	Chlorophylls	Chlorophyll A and chlorophyllin
6.	Terpenoids	limonin and limonene
7.	Allylic Compounds	Diallyl sulfide and disulfide
8.	Indoles	Indele-3-carbinol

Recent evidence strongly suggests that eating plenty of antioxidant – rich plant foods may reduce the risk of chronic diseases. It is hypothesised that phytochemicals present in plant foods exert beneficial effects by combating oxidative stress in the body through maintaining a balance between oxidants and antioxidants. Polyphenols can act chemically as antioxidants due to their extensive conjugated π-electron system, which allows ready donation of electrons or hydrogen atoms from the hydroxyl moieties to free radicals, which causes antioxidant activity.

Polyphenols are low molecular weight compounds found in commonly consumed plant foods, e.g. fruits, green leafy vegetables (GLVs), vegetables, nuts and oil seeds, etc. They are important to plants wherein they acts as antioxidants, enzyme regulators and precursors of toxic substances. Since different antioxidants work in different ways and in different places in the body, it is important to eat a variety of foods to get various antioxidants.

Judicious selection and consumption of plant foods rich in polyphenoilc antioxidants could therefore be of great help in modulating the oxidative stress and associated diseases in the population.

25.7 Food Allergy and Food Intolerance

UV Mani

The importance of food comprising of macro, micro and other health promoting nutrients required for the growth and development of human life from conception to senescence is well known since the time immemorial. Extensive studies on the physicochemical and nutritional aspects of foods have also brought out various deleterious effects of some foods and food components in causing various health problems.

Allergy is one of the side-effects of immunity develops under some conditions. There are several different types of allergies, some of which can occur in any person, and others that occur only in persons who have a specific allergic tendency.

FOOD ALLERGY

Food allergy is recognised as a common worldwide problem and, like other atopic disorders, its incidence seems to be increasing. Any abnormal clinical response associated with ingestion of a food or food additive is generally termed as food allergy. These adverse reactions can be further classified as food allergy and food intolerance depending on the type of mechanism involved. Food allergy refers to an abnormal immunologic response to a food that occurs in a susceptible host. Food allergy can be IgE-mediated, mixed IgE and cell-mediated.

Epidemiology

The prevalence of food allergy is highest in infants and toddlers. Cow's milk allergy is experienced by 2.5% of infants and up to 8% of children less than three years of age. The prevalence of food allergy decreases slightly with age, affecting almost 4% of the general population.

Aetiology

The diverse clinical manifestations of food allergy result in part from different immune mechanisms, target organ responses, and characteristics of triggering proteins. Conceptually, it is useful to categorise the immune mechanisms according to three general types—IgE antibody-dependent diseases (triggered by multiple foods, raw fruits and vegetables), cell-mediated disorders without detectable IgE antibodies (triggered by egg, milk, wheat and soy) and disorders with mixed IgE and non-IgE mechanisms (triggered by wheat, lactose, fructose and some food additives). The development of allergy frequently starts in early childhood with initial eczema, followed by the subsequent sequential development of food allergy, allergic rhinitis, and asthma—the so-called 'atopic march'. Allergic diseases are also an example of gene-environment interactions.

Clinical Features

Allergic reactions to foods generally occur within a few minutes to one hour after eating the offending food which range from mild discomfort to severe life-threatening reactions. Symptoms can last for days or even weeks. The specific symptoms and severity of an allergic reaction are affected by the amount of the allergen consumed and the sensitivity of the allergic person.

Diagnosis

The evaluation of a patient with a possible allergic food reaction begins through clinical history and a complete physical examination to consider a potentially broad differential diagnosis between food-induced allergic clinical disorders and other gastrointestinal diseases, such as food intolerance (toxic and pharmacological effects or metabolic disorders), infections (viral, bacterial and parasitic), coeliac disease, inflammatory bowel diseases, bowel ischaemia, gall bladder disease, pancreatic insufficiency, and gastrointestinal neoplasms.

Management

Once a food allergy is diagnosed, strict elimination of the offending food allergen from the diet and avoidance of any contact with the food by ingestion, skin contact, inhalation, or injection is necessary. Thus, the primary therapy for food allergy is to avoid the causal food. Clinical tolerance develops to most food allergens over time, except for peanuts, nuts and seafood. Periodic re-introduction of food allergens under physician supervision is warranted to determine whether clinical tolerance has developed or not. There is a relationship between the decrease in serum food-specific IgE concentrations and the likelihood of developing tolerance. A greater decrease in serum food specific IgE levels over a shorter period of time might be indicative of a greater likelihood of developing tolerance.

Prevention

Approaches to delay or prevent allergy through dietary manipulation have been considered. Some studies suggest a beneficial role for exclusive breastfeeding of infants at high-risk for atopic diseases in the first 3 to 12 months of life and avoidance of supplementation with cow's milk or soy formulas in favour of hypoallergenic formulas if breastfeeding is not possible. Maternally ingested food can pass in immunologically intact form into breast milk and might induce reactions in infants. No conclusive studies indicate that manipulation of mother's diet during pregnancy or breastfeeding or the restriction of allergenic food from the infant's diet will prevent the development of food allergy whereas the introduction of solid can be delayed until 6 months of age and major allergens, such as peanuts, nuts and seafood, be introduced after 3 years of age till the child develops its own immunity.

Supplementation of antioxidant vitamins and minerals showed some good results in prevention of food allergy. It is postulated that an allergic response to antigen challenge, including inflammatory cell infiltration, results in the generation and release of reactive oxygen species. These oxygen free radicals lead to bronchoconstriction, increased mucus secretion and microvascular leakage.

Thus, by carefully analysing the causes and further by eliminating those causative agents, it is possible to overcome and control this disorder.

FOOD INTOLERANCE

Food intolerance (FI) reactions comprises of metabolic, pharmacologic, and gastrointestinal responses to foods or food compounds. It is a negative reaction, often delayed to a food, beverage, food additives or compounds present in the foods which produce symptoms in one or more organs and systems. In most cases, food intolerance is not associated with the production of IgE antibodies whereas food allergy does. Therefore, food intolerance is generally not life-threatening.

Aetiology

The various organic chemicals present in a wide variety of foods, both of animal and vegetable origin, food additives, (colouring and flavouring agents) preservatives, (monosodium glutamate) and many food chemicals have been identified as the causative agents.

A deficiency in digestive enzymes can also cause some types of food intolerance. Lactose intolerance is a result of the body not producing sufficient lactase to digest the lactose in milk, dairy foods, such as cheese. Another carbohydrate intolerance caused by enzyme deficiency is hereditary fructose intolerance.

Coeliac disease is an autoimmune disorder caused by an immune response to the protein gluten found in many foods (wheat, rye, barley and to some extent oat) which results in gluten intolerance and can lead to temporary lactose intolerance also.

The most widely distributed naturally occurring food chemical capable of provoking reactions is salicylate although tartrazine and benzoic acid are well recognised in susceptible individuals. Benzoate and salicylate occur naturally in many different foods, including fruits, vegetables, spices, herbs, nuts, tea, wines, and coffee, besides salicylates being present in pharmacological source such as aspirin and nonsteroidal anti-inflammatory drugs.

Other chemicals which commonly cause reaction and cross-reactivity include amines (banana, chocolate, cheese, tomato, etc.) nitrates and sulphites (in processed food) and some chemicals involved in aroma and flavour. Since the threshold levels vary in individuals, the consumption of large quantity of a single causative factor or many causative factors in a small quantity will result in FI of different degrees. FI can also occur as a secondary manifestation to an in-born error of metabolism (phenylketonuria and favism). Food intolerance can also be psychological in origin if the symptoms are triggered by emotional responses to the food in question.

Clinical Features

Symptoms of food intolerance vary greatly and can be similar to the symptoms of food allergy. Food intolerance symptoms usually begin within half an hour after consuming the food in question, but sometimes the symptoms may appear even after 48 hours. Food intolerance can present with symptoms affecting the skin, respiratory tract, gastrointestinal tract (GIT) either individually or in combination. On the skin, there may be skin rashes, urticaria (hives), angioedema, dermatitis and eczema. Respiratory tract symptoms can include nasal congestion, sinusitis, pharyngeal irritation, asthma and an unproductive cough. GIT symptoms include mouth ulcers, abdominal cramp, nausea, gas, intermittent diarrhoea, constipation and irritable bowel syndrome. Estimates of prevalence of food intolerance vary widely from 2% to over 20% of the population.

Diagnosis and Management

The easiest test for food intolerance is to remove the food from the diet and see if symptoms improve and disappear. If the symptoms appear on re-introduction of the food, presence of FI is confirmed.

Lactose intolerance can be tested more thoroughly using a lactose intolerance test, a hydrogen breath test and stool acidity test.

Food intolerance can be managed simply by eliminating the causal food from the diet. It is also useful to avoid foods with additives which may cause FI. If the sensitive food chemicals are identified, an appropriate diet can be prescribed excluding those food chemicals with the help of a dietician. The treatment involves consumption of gluten free diet. Among the cereals, only rice, corn and possibly oats can be used. It is not advisable to eat pasta, salad dressing and some margarine because they contain wheat or wheat extractsand also drinking beer should be avoided.

25.8 Eating Disorders

Anupam Prakash

INTRODUCTION AND EPIDEMIOLOGY

Eating disorders are characterised by a severe and persistent disturbance in eating behaviour that causes psychosocial and sometimes, physical impairment.

Anorexia nervosa (AN) and bulimia nervosa (BN), the two distinct forms of eating disorders, are 10 times common in females and the prevalence of the two disorders among females is respectively, 0.5% to 1% and 1% to 3%. The onset of the AN is observed in mid-adolescence and for the latter BN in late adolescence to early adulthood. Eating disorder 'not otherwise specified' (NOS) is observed usually in middle-aged, and the female sex predilection is absent and is observed in obese individuals. Eating disorder NOS is the most common eating disorder encountered in clinical settings constituting about half of adult outpatient eating-disordered population, with patients of bulimia nervosa constituting about a third, and the rest being cases of anorexia nervosa. In inpatient settings, the great majority of cases are either underweight forms of eating disorder NOS or anorexia nervosa.

Since eating disorders were originally identified, the relationship between obsession with food and that with body weight has been consistently debated. It is also important to understand the particular way in which people with eating disorders perceive their bodies in the presence of other people.

Two notions are fundamentally important: 'body-self' and 'body-for-others'. The 'body self' is understood as the basis of self consciousness and inter subjectivity. 'Body-for-others' means how one experiences one's own body when someone else is looking at it and the subject body thus becomes conscious of being a body-object for others. Apart from a combination of psychological, biological and cultural risk factors; genetic factors also contribute to the risk of development of eating disorders. The exact aetiology hitherto remains unknown.

CLASSIFICATION AND DIAGNOSTIC CRITERIA

Psychiatric diagnosis are categorised by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition (DSM IV). Eating disorders are an extremely heterogenous diagnostic category. DSM IV recognises two eating disorders in adults, AN and BN; and a residual category-eating disorder not otherwise specified (EDNOS).

Two subtypes each for AN and BN have been identified, depending upon the method adopted by the patients to control their weight: restricting type (AN-r) and binge-/purging (AN-p) for AN and purging/non-purging type for BN.

The diagnosis of AN is made in the presence of the following features:

1. The over evaluation of body shape and weight; that is, judging self worth largely, or even exclusively, in terms of shape and weight. This has been described in different ways and is often expressed as strong desire to be thin combined with an intense fear of weight gain and fatness.
2. The active maintenance of an unduly low body weight; this is commonly defined as maintaining a body weight less than 85% of that expected or a body mass index (BMI) of 17.5 or less.
3. Amenorrhoea, in post-pubertal females not on oral contraceptive; this criterion is proposed to be removed in DSM V.

For a diagnosis of BN, the following three features need to be present:

1. Over evaluation of body shape and weight, as in AN.
2. Recurrent binge eating: A 'binge' is an episode of eating during which an objectively large amount of food is eaten for the circumstances and there is an accompanying sense of loss of control.
3. Extreme weight-control behaviour, such as recurrent self-induced vomiting, regular laxative misuse, or marked dietary restriction.

In addition, the diagnostic criteria for AN should not be met. This ensures that the two diagnosis are mutually exclusive. Hence, the BMI becomes a distinguishing feature between the two.

There are no positive criteria for the diagnosis of eating disorder NOS. Instead, this diagnosis is reserved for eating disorders of clinical severity that do not meet the diagnostic criteria of AN or BN. However, under the rubric of eating disorder NOS, DSM IV lists 'binge eating disorder' (BED). It is proposed that BED should be recognised as a specific eating disorder in DSM V.

CLINICAL FEATURES

Eating disorders share a common psychopathology, the over evaluation of the importance of body shape and weight, and their control. For people with eating disorders, self worth is dependent largely, or even exclusively, on their shape and weight and their ability to control them. The salient features of various eating disorders are outlined in **Table 1**.

Anorexia Nervosa (AN)

Patients become underweight, either because of persistent and severe restriction of both the amount and the type of food that they eat, or because of adopting a driven form of exercising. Anorexia nervosa patients typically value the sense of control that they derive from undereating. A subgroup of anorexia nervosa patients practice self-induced vomiting, laxative and/or diuretic misuse, especially those who experience episodes of loss of control over eating. Interestingly, the amount of food

eaten during these 'binges' is often not objectively large; hence, they are described as 'subjective binges'. Many other psychopathological features tend to be present and include depressed and labile mood, anxiety features, irritability, impaired concentration, loss of libido, obsessions to a varied extent and social withdrawal.

A hierarchical relationship in order of severity has been proposed:

(a) AN and behaviourally similar disorders — most severe
(b) BN and behaviourally similar disorders
(c) BED and behaviourally similar disorders
(d) Eating disorder NOS — least severe

Table 1: Salient Clinical Features of Eating Disorders

	Anorexia Nervosa	Bulimia Nervosa	Binge-Eating Disorder	Eating Disorder NOS
Age of onset	13 to 25 years	16 to 35 years	25 to 50 years	25 to 50 years
Sex predilection	Female (10:1)	Female (10:1)	None	None
BMI (kg/m^2)	<17.5	18.5 to 25	>25	Normal to high
Menstruation	Amenorrhoea	Normal	Normal	Normal
Restrictive eating	Criterion for diagnosis	Absent	—	—
Binge-eating	May be seen in 25% to 50%	Criterion for diagnosis	Intermittent, absent compensatory behaviour	Variable
Suicidal ideation	Yes	Rare	—	—
Mortality	Approx. 5% per decade	Low to nil	—	—
Physical characteristics	Physical overactivity, lanugo hair on trunk and limbs, oedema, azotaemia, anaemia, leucopaenia, sialadenosis, delayed gastric emptying, constipation, hypoglycaemia hypokalaemia, hypomagnesaemia, metabolic alkalosis, osteopaenia, hypotension, bradycardia, acrocyanosis	Less common. Hypokalaemia, hyponatraemia, hypomagnesaemia, metabolic alkalosis, dental caries, enamel erosion, sialadenosis, azotaemia, arrhythmias	Complications related to obesity, limited ability to lose weight	—

Bulimia Nervosa

It resembles BN, both in terms of eating habits and methods of weight control, but the distinguishing feature is that attempts to restrict food intake are regularly disrupted by episodes of (objective) binge eating. These episodes are often followed by compensatory self-induced vomiting or laxative misuse, although there is also a subgroup of patients who do not purge (non-purging BN). Due to this combination of under eating and over eating, the weight of most patients with BN tends to be unremarkable and is within the healthy range (BMI = 20–25 Kg/m^2). Features of depression and anxiety are prominent in these patients. Rarely, these patients can engage in self harm and/or substance and alcohol abuse. Physical complaints are much less common, although electrolyte disturbance may occur in those who vomit or take laxatives or diuretics frequently.

Binge-Eating Disorder (BED)

This disorder refers to a clinical picture characterised by recurrent binge eating in the absence of the extreme weight-control behaviour seen in AN and BN. In fact, BED is rather different from AN and BN, and from the many presentations relegated to eating disorder NOS. Those affected tend to be middle-aged rather than adolescents or young adults, the marked preponderance of females is absent, and the state commonly co-occurs with obesity. Patients of BED invariably have a BMI >25 Kg/H^2 (are overweight or obese). Furthermore, in marked contrast to AN and BN, BED tends to be intermittent rather than continuous with many individuals reporting sustained periods when they are free from binge-eating.

MANAGEMENT

Anorexia Nervosa (AN)

The primary management is restoration of weight to at least 90% of the normal. However, this is greatly resisted by the patients and consequently is accompanied by frustration. Therefore, counselling of the patient is imperative. Patients with suicidal ideations and with serious medical complications need to be admitted. Otherwise outpatient counselling sessions providing behavioural therapy and interpersonal psychotherapy along with requisite nutritional advice can be provided. Family-based therapy can be used for adolescents. Behaviour therapy focuses on gaining control and changing unwanted behaviours. Drug therapy, including psychotropic drugs, is not found to be useful in AN. However, selective serotonergic reuptake inhibitors may be useful for treating comorbid anxiety or depression. The prognosis is good in the short-term, but long-term outlook is variable. One-fifth make a full recovery and one-fifth remain chronically ill, while the remaining have recurrent episodes of anorexia. Mortality from suicide or physical complications is reported at the rate of 5% per decade.

Bulimia Nervosa (BN)

Cognitive behavioural therapy is the treatment of choice. Cognitive behavioural therapy is a short-term, i.e. 4 to 6 months psychological treatment and produces symptomatic remission in 25% to 50% of patients. Interpersonal therapy is also beneficial. Fluoxetine or other selective serotonergic reuptake inhibitors can be used for bulimia symptoms and the latter can

also benefit co-morbid symptoms. BN patients can be treated on outpatient basis and usually do not require admission. The prognosis is far better than AN patients and mortality is unusual.

Eating Disorder Not Otherwise Specified and Binge-Eating Disorder

Group or individual cognitive behavioural therapy has been found to be beneficial. Sibutramine or orlistat was being used for weight loss and selective serotonergic reuptake inhibitors for co-morbid depression or anxiety. Sibutramine has been banned and recent reports of orlistat causing hepatotoxicity have made its use controversial at the moment.

CONCLUSION

Eating disorders are severe psychological illnesses and are associated with significant physical and psychological disturbances in turn compromising the quality of life. It is important to realise that eating disorders form a spectrum of disorders across different age groups and varying body proportions. It is imperative to be aware of these disorders to make an early diagnosis and provide multidisciplinary therapy for restoration of health in these patients.

25.9 Enteral and Parenteral Nutrition

Varsha

INTRODUCTION

Clinical nutrition can significantly improve patient care in hospitals. Until antibiotics were developed the combination of poor nutrition and infection contributed to the significantly high morbidity and mortality associated with many hospital admissions, particularly for patients needing surgical operations. Since infections can be largely overcome, the dangers of poor nutrition to malnourished patients, with serious illnesses remains highlighted. So much more needs to be done and must be done both in the assessment and management of sub-optimal nutrition in hospitals.

"Sick patients do not oblige their doctors by separating 'metabolic' from 'tissue pathology' states. The whole problem must be solved together, not in sections" (Francis D Moore, 1959). Definition of 'Critical illness', in itself indicates the depth and magnitude of what the Francis Moore statement wishes to convey – its primarily a metabolic response to injury, and is secondary to a wide range of conditions, such as trauma, burns, systemic infection (sepsis), severe head injury, sterile inflammatory processes, etc. Needless to state the macronutrients and the micronutrients permutations and combinations would work out an astronomical figure when one begins fitting the puzzle of a perfect prescription for a sick individual. There are no shortcuts and the vista is yet unchartered for evidence-based documentation on the formulations that would work well not only in just prolonging life, but also to support healing with resultant good quality of life. If this were the basis for formulating nutrition support, it should work well. It is on this that Nutritional Support (NS) was started and has grown in popularity and it is now a multibillion dollar-a-year industry. This growth was and is still spurred by the assumption that such an intervention would improve patient outcome. The reasons of this multinational support are outlined in **Table 1**.

Table 1: The Basis of this Wide Acceptance of NS (Parenteral NS ENS – PNS) Rests on 5 Lines of 'Reasoning'

1. Any living organism, when deprived of nutrient intake for a long enough period, will die.
2. An individual with a given disease who is also malnourished has a poorer prognosis than does one with the same disease but who is not malnourished (Studley's observation).
3. NS improves measured parameters of malnutrition (especially such things as body weight or nitrogen balance).
4. Retrospective or prospective (with or without nonrandomised control groups) reports allegedly demonstrate therapeutic efficacy.
5. Doing something is better than doing nothing.

Translating knowledge into practice is always difficult clinical exercise. It seems appropriate that every hospital will have organised and effective clinical nutrition service, since there is a quantum leap in the concept that has not kept pace with the formulations of products. The original concept was "The Classic Approach to Nutrition Support" that centered on maintenance of Body Cell Mass (BCM) and Nitrogen Balance (NB) and its measurements to assess the effectiveness of NS. It must if not totally, be replaced to accommodate the more advanced concept of The Contemporary Approach to Nutritional Support that *recognises the multi-factorial nature of illness*: such as alteration of the stress response, administration of tissue-specific nutrients [arginine, glutamine, etc.]; stimulation or administration of growth factors is the GOALS of NS. Hence, the immediate translation of this new concept in understanding the importance of nutrition to critically ill patients (**Table 2**), would mean maintenance of organ function and immune status and improvement in clinical outcome more important than maintenance of BCM or NB. NS is currently in a dynamic phase fostered by knowledge from molecular biology, and it equates to 'improves the efficiency and effectiveness of NS'.

Table 2: Importance of Nutrition to Critically Ill Patients

Goals for nutrition support – *to meet the demands of accelerated energy and nitrogen flux as progressive protein-energy malnutrition (PEM) appears to increase morbidity and mortality*

1. Early detection and correction of pre-existing malnutrition
2. Prevention of progressive PEM
3. Optimisation of the patient's metabolic state (including provision of fluid and electrolytes)
4. Reduction of morbidity, and
5. Reduction of subsequent duration of recovery.

Prospective randomised and double blind studies on the efficacy on NS in malnourished patients with curable or reversible disorders are unethical given the present state of knowledge and experience. NS is indicated in the following patients:

1. A previously well-nourished patient with actual or expected complications or with 'stress', e.g. infections, polytrauma.
2. A previously well-nourished patient who has not consumed sufficient oral nutrition for 5 to 7 days prior to admission.
3. A patient found to be malnourished on admission.

The information is pertaining to the existing scenario and one must begin by looking at the learning objectives that govern nutritional support's two arms: enteral nutrition (EN) and parenteral nutrition (PN) and their access devices, formulations, implementation, complications and management.

The introduction of chemically defined foods led on to the development of parenteral feeding, which has such life-saving potential for many seriously ill patients. However, EN is physiological and is superior to PN in terms of cost, reduced complications, ease of maintenance, efficacy of nutritional repletion, and maintenance of organ function. Providing even 'token' EN diminishes gut mucosal atrophy and maintains gut integrity thereby preventing translocation of bacteria and toxins from the gut into the circulation. It is this translocation that results

in the 'Stress Syndrome'. Peristalsis is NOT necessary for absorption of nutrients from the ileum. If access into jejunum is achieved, nutrients can be infused in the absence of bowel sounds, immediately after laparotomy and with 'ileus' Nasogastric suction (as in the management of stress-induced gastritis, gastric atony, etc.) is not a contraindication for distal feeding into the jejunum.

INDICATIONS FOR NUTRITIONAL SUPPORT

The key biochemical concept to remember in critical care is that stressed starvation is not the same as simple starvation. In the former, hypermetabolism (increase in resting energy expenditure) and hypercatabolism (loss of lean tissue, negative nitrogen balance) occur due to hormonal changes. Counter regulatory (or 'anti-insulin' hormones) such as catecholamines cortisol and glucagons are all elevated. While circulating insulin levels are also elevated as there is a relative insulin-resistance. Unless an attempt is made to decrease this 'autocannibalism', loss of protein results in death.

Guidelines for protein, carbohydrate, and fat are the same for EN and PN. Besides this, the *route of delivery* is equally an important integral factor in outcome. An algorithm delineated (**Table 3**) with respect to determining the appropriate route of delivery.

ENTERAL NUTRITION

Access

Oral, nasogastric, nasojejunal, gastrostomy or Jejunostomy (needle catheter or tube).

Enteral Infusates/Formulations

Commonly classified as elemental or non-elemental. The elemental diets are said to be better tolerated. However, the human gut is capable of absorbing complex moieties just as well. A disadvantage of elemental diets is their high carbohydrate content. Modular changes in EN (i.e. specific addition of protein, fat or carbohydrate as needed to standard commercially available formulae) are required for optimal National Status (NS). Formulae enriched with glutamine (to preserve gut integrity), fibre (to improve tolerance and to stimulate gut mucosa by virtue of degradation to short chain fatty acids) and omega-3 fatty acids with RNA (to stimulate immunity) are commercially available but their superiority in nutritional repletion has not been convincingly proven.

Appropriate formula selection is important and an integral component of successful enteral tube feeding. First modern enteral formulas were homemade from blenderized foods diluted enough to pass through a feeding tube. The inherent problems were: difficulty with consistency and lack of nutrient standardisation.

Modern enteral formulas have evolved over these years (**Table 4**) and designed to meet patient nutrient requirements in a specified volume of formula. The basis of this evolution, however, has been the understanding of the patient's digestive and absorptive capacity that influences the selection of formula composition, e.g. one must be aware of the following facts:

1. Gastric atony associated with sepsis may limit the use of direct intragastric feedings.
2. Limiting enteral feeding is advised in haemodynamically unstable patients because of reduced splanchnic blood flow.
3. Gastric feeding should be carefully monitored to avoid high gastric residuals and pulmonary aspiration.

The different categories of enteral formulations are given in **Table 4**.

Table 3: Determining Route of Nutrition Support

TPN
Yes ↓
TPN

Intestinal obstruction - bowel use X?
No ↓
Paralytic ileus?
Yes ↓ TPN
No ↓
Pancreatitis?
Yes ↓
Pancreatitis severe?
– Pancreatic pseudocyst
– Pancreatic ascites
– Pancreatic haemorrhage
– Pancreatic infection
– Pancreatic phlegmon
– Severe pain?

- Oesophagus
- Stomach
- Duodenum
- Proximal jejunum? Or 150 cm ileum?
Yes ↓ EN distal to fistula
No ↓ TPN
No ↓
Severe short bowel syndrome < 100 cm jejunum
Yes ↓ TPN
No ↓ EN

Table 4: Enteral Formulations: Categories

Type	Comment
Polymeric diets	Whole protein nitrogen source, for use in patients with normal or near normal GI function
Monomeric diets	Predigested nutrients; most have a low fat content or a high percentage of medium chain triglycerides for use in patients with severely impaired GI function
Fibre containing	Polymeric diets containing source of fibre; diets reportedly beneficial for prevention/ treatment of altered bowel function in enterally fed patients
Disease specific	Formulas designed for feeding patients with specific disease states – now available for patients with respiratory disease, diabetes, renal failure, hepatic failure, and immune compromise, well-designed clinical trials may or may not be available

Mode of Infusions: Bolus, Cyclic, Continuous

With respect to bolus mode, though there are disadvantages it is physiological mode of feeding. Continuous feeding is unphysiological as glucose stimulates release of insulin, which in turn decreases lipid mobilisation. In cyclic feeding, either the infusion is interrupted for 4 to 6 hours each day or a glucose-free solution with decreased amount of intracellular ions (K, Mg, and P) is infused. Better nutritional repletion and a decrease in liver-enzyme elevation occurs. However, managing fluid balance and glucohomeostasis in an ICU patient is difficult with cyclic feeding.

Developing Enteral Formulary

Criteria used for selecting EN products included on the enteral formulary are depicted in **Tables 5A to D** and **Table 6**.

Table 5A: Carbohydrate (CHO) Source and Quality

Generally provided using combination of:
- Hydrolysed cornstarch
- Maltodextrins
- Corn syrup solids, and/or
- Sucrose

Form of carbohydrate (CHO)
- Influences osmolality, sweetness and digestibility of the enteral product – Monosaccharides; Oligosaccharides 2-8 units; Polysaccharides >8 units
- Most CHO except Lactose, easily digested, absorbed by the small bowel
- CHO content of formulas ranges from approx. 40% to 90% of total caloric content
- Symptoms of CHO intolerance range from abdominal discomfort to flatulence and diarrhoea

Table 5B: Protein Source and Quality

Amount ranges from 4% to 32% of total calories
- Low protein (<10%) – when restriction – renal failure
- Standard protein (11% to 15%) – when no increased requirements
- Intermediate protein (16% to 20%)
- High protein (>20%) – in increased nitrogen requirements – e.g. trauma, burns, etc.

Commercial formulas
- Intact protein
- Protein hydrolysates
- Crystalline amino acids

Table 5D: Electrolyte, Mineral Content, and Vitamin Content (Volume Necessary to Supply RDA)

Most enteral products meet 100% of RDA at a given volume of formula (excluding renal and hepatic formulas)

However, RDAs do not reflect needs during critical illness or severe hypermetabolism – hence manufacturers adopt different reference standards

Of current interest – relationship between β-carotene and immune function - β-carotene may increase cytotoxicity of natural killer cells, enhance immune response, and increase levels of T-helper cells

Presently six enteral products contain β-carotene

Developing Enteral Formulary: Conclusions

I. Appropriate formula selection requires knowledge about
   - The nutrient requirements of specific patient populations
   - Awareness about the potential effects of formulas on gastrointestinal, metabolic and immunologic functions.

II. Critical evaluation of formula composition to ensure efficacy and safety of product use: Formulas developed for particular disease states or clinical conditions – supported by well-designed clinical trials.

III. Enteral nutrition products: Market significant >80 products.

IV. Choices include:
   - Formulas with peptides, fibre and β-carotene
   - Formulas, disease specific
   - Formulas designed to improve immune function

V. Can current standard formulations be improved?
   1. Are specific nutrients being given in excessive amounts, i.e. chromium and manganese?
   2. Is there still too much contamination with toxic minerals, i.e. aluminum?
   3. Are there nutrients and non-nutritional factors present in foods that will be beneficial if added to purified formulas?

Table 5C: Fat Source and Quality

FAT: Essential fatty acids (EFAs)

Fat provides an isotonic, concentrated energy source

Fat content of ENF ranges from <10% to >50% of total calories

Fat sources in enteral products – soy, corn – more frequently used, safflower and sunflower oils; canola oil, beef fat, refined marine fish oil – less frequently used, medium-chain triglycerides (MCT's), and structured lipids

Many products contain fats that do not provide adequate quantities of both linoleic (w-6 – 1-2% total calories) and linolenic (w-3 – 0.2-0.3% total calories) acid

FAT: Medium chain triglyceride (MCT)

Quickly hydrolysed intraluminally, increased levels of intake may increase the luminal osmotic concentration and cause abdominal distension and diarrhoea

Metabolised in the liver – ingestion of high levels contraindicated in cirrhosis – may induce a situation similar to hepatic encephalopathy

MCTs ketogenic – not be given to hyperosmolar diabetic syndrome patients

Table 6: Physical Characteristics of Enteral Formulations (EFs)

Osmolality

Enteral products range in osmolality from 270 mOsm/kg to approximately 700 mOsm/kg - as a general rule, do not worry about diets whose osmolalities are 350-450 mOsm/kg water or less, *except* when fed directly into the duodenum or jejunum

Osmolality may affect patient tolerance to a particular formula – hypo- and hyperosmolar feedings delay gastric emptying

Hyperosmolar formulas may increase intraluminal osmotic concentration and create GI intolerance - the importance of hypertonicity in causing diarrhoea has probably been overestimated

If the osmotic load relative to free water exceeds the ability of the kidney to concentrate, an osmotic diuresis results, leading to dehydration

Nutrient Density (ND)

1. Calorie-Nutrient Density – may affect tolerance of tube feeding by its effect on gastric emptying
   a. The greater the ND (kcal/mL) the slower the emptying rate into the duodenum
   b. Tolerance of a particular formula – fat, most powerful inhibitors of gastric motility – high intakes or rapid infusion into the duodenum – a significant delay in gastric emptying
   c. A consideration when initiating enteral feedings, especially in GI tract compromised patients – not used for an extended period or have mucosal disease/damage
2. Introduce nutrients gradually in a diluted or low-calorie formula – not to exceed the capability of the intestinal enzymes to hydrolyze the nutrients

Approximate water content of EFs based on caloric density

Caloric density (kcal/mL formula)	Water content (kcal/H20/1000 mL formula)	Water content (%)
1.0 -1.2	800-860	80-86
1.5	760-780	76-78
2.0	690-710	69-71

pH

Solutions with a pH of less than 3.5 reduce gastric motility

Not a major concern with most commercial formulas

Residue

1. Many formulas contain little or no residue
2. May be advantageous in the management of specific gastrointestinal disorders (e.g. bowel fistula or enteritis)
3. Low-residue diets may cause constipation in some patients

Complications

1. Aspiration pneumonitis.
2. Diarrhoea (due to hypoalbuminaemia, antibiotics, organisms). The use of intravenous albumin to improve tolerance to EN is controversial.

PARENTERAL NUTRITION (PN)

Access

Peripheral IV cannulae or central (single or multiluminal) catheters. Catheter insertion and care should follow established protocols.

PN Formulation Components

1. Energy substrates – carbohydrate and lipids
2. Protein
3. Electrolytes
4. Vitamins
5. Trace elements
6. Water

Various combinations of these components are incorporated into the regimen for IV administration based on the patient's individual needs and clinical limitations. Parenteral feeding imposes increased risks, major expense, and a serious handicap. Current clinical data on commercially available parenteral nutrition solutions – not embraced the new approaches (**Tables 7A to F**).

Several amino acid solutions with varying concentrations with or without added electrolytes and major minerals are available. Dextrose solutions vary in concentration from 10% to 70%. A trained pharmacist usually does mixing. Fat emulsions are available as 10% or 20% solutions. The convenience and safety of 3-in-1 admixtures have made this popular. All components of PN are mixed in one high-volume bag and provided to the patient. While there are theoretical reasons to provide branched-chain amino acid-enriched infusates to stressed patients; the cost-effectiveness of its routine use has not been demonstrated.

PN Formulation Conclusions

1. Parenteral feeding imposes increased risks, major expense, and a serious handicap.
2. Current clinical data on commercially available parenteral nutrition solutions – not embraced the new approaches.

Table 7A: Energy Substrates – Protein

Crystalline amino acids – 4.0 kcal/g

Amino acids: Standard – provide EAA and Non-EAA

Standard amino acid (STD AA) formulations, based on egg protein – the workhorse for providing nutrients during the formative years of parenteral nutrition – this approach sought to provide nutrients for total-body nitrogen utilisation

Table 7B: Energy Substrates – Carbohydrate

Dextrose – hydrated – 3.4 kcal/g – multiple concentrations range from 2.5% to 70%

Dextrose – acidic – pH range 3.5 to 6.5 – osmolarity vary depending on concentration

Higher concentrations of dextrose (>10%) reserved for administration via a central vein due to propensity to cause thrombophlebitis in peripheral veins

Sugar alcohol glycerol – less frequently used – 4.3 kcal/g – protein sparing – ?induces less insulin response than dextrose-based regimens

Dextrose solutions

70% = 2.38 kcal/mL
50% = 1.70 kcal/mL
40% = 1.36 kcal/mL
30% = 1.02 kcal/mL

Table 7C: Energy Substrates – Lipid – Emulsion – Energy and EFA

10% - 1.1 kcal/mL

20% - 2.0 kcal/mL

30% - 3.0 kcal/mL – not for direct administration

Soyabean oil or 50:50 mix of safflower and soyabean – other components of lipid emulsions – egg yolk phospholipid (emulsifier) – glycerin (to render formulation isotonic) – vitamin K and sodium hydroxide to adjust the final pH (range 6.0-9.0)

Metabolic fate of lipid emulsions – issue of concern – lipids are not completely oxidised – during stress increased re-esterification of FFA into triglycerides and deposition into storage tissues and large amounts of lipid emulsion at rapid infusion rates result in compromised function of granulocytes, leucocytes, neutrophils, and phagocytes and decreased T-helper: T-suppressor cell ratios

Hence, accepted method for Tx – provide 500 ml of a 10% IV fat emulsion 2 to 3 times weekly

The practice of providing fat in 3-in-1 solutions (i.e. fat-CHO-protein) or total nutrient admixtures (TNAs) standard

Long-chain IV fat emulsions – for Tx of EFAD and as parenteral caloric source, provides a dense caloric source with minimal fluid volume to the patient

For clinical situations requiring 4 to 7 kcals/kg/d fat emulsions be prescribed and administered

A baseline serum triglyceride level should be obtained and triglycerides monitored biweekly

Table 7D: Vitamins

Single entity products and combinations of both fat-soluble and water-soluble vitamins

Multivitamin for adults – typically include vitamins A, D, E, C (ascorbic acid), B_1 (thiamin), B_2 (riboflavin), niacin, folic acid, B_6 (pyridoxine), pantothenic acid, biotin, B_{12} (cyanocobalamin).

Vitamin K (if ordered) – added to the PN formulation separately or administered subcutaneously

Pediatric formulations – pediatric doses of the same as listed above + vitamin K

Vitamins marketed as single entry injectible products include all of the above except biotin, pantothenic acid, riboflavin, vitamin A and vitamin E

Carnitine necessary for proper transport and metabolism of fatty acids – IV form of L-carnitine available

Complications

1. Catheter malfunction and sepsis; 2. Electrolyte and mineral deficiency; and 3. Glucose intolerance. Warning: Do Not Overfeed! hypophosphataemia and hypokalaemia can occur with lethal results during the 'refeeding syndrome'.

Developments in PN

1. Medium-chain triglycerides (MCT) containing formulas since it is carnitine-independent for transportation into mitochondria.
2. Glutamine-enriched formulas, as glutamine is vital for gut environment.
3. Carnitine and RNA enriched formulas, as these are implicated in enhancement of immune function.
4. Hormones supplementation (e.g. human growth hormone) that promote positive nutritional status.

Table 7E: Electrolytes

Standard daily ranges include:

Sodium (Na) and Potassium (K)	: 1-2 mEq/kg + replacement of losses
Calcium (Ca)	: 10-15 mEq
Magnesium (Mg)	: 8-20 mEq
Phosphate (P)	: 20-40 mmoL

Acetate and chloride – no specific ranges for intake – adjusted as needed to maintain acid-base balance

Electrolytes available in salt forms

- Na and K – chloride, acetate, and phosphate
- Ca – chloride, gluconate, glycepatate
- Mg – sulphate, chloride
- Generally gluconate salt of Ca and sulphate salt of Mg preferred forms of cations – less likely to produce physicochemical incompatibilities

Trace Elements

- Adults, paediatrics, neonates – with or without electrolytes commonly used in PN
  - Zinc (Zn), Copper (Cu), Chromium (Cr), Manganese (Mn), Selenium (Se)
  - Other Trace Elements (TE)? may be included
    - Molybdenum (Mo), Iodine (I), Iron (Fe – available only as a single-entity product)

Table 7F: Volume Aspects

Sterile water for injection – used to provide necessary fluid and volume to the PN feeding formulations

Critically ill patient presents a challenge in fluid management

TPN + other IV fluids given for concurrent medical problems – i.e. antibiotic, cardiac and pulmonary therapy.

To minimise fluid overload, considerations be given to using concentrated solutions to provide nonprotein kilocalories and protein

MONITORING OF NUTRITIONAL SUPPORT

Nutritional Monitoring

Weight gain, serum total protein and albumin levels, and nitrogen balance, total lymphocyte count.

Fluid Status Monitoring

A negative balance during repletion is common due to mobilisation of intracellular water. In EN, the amount of free water in infusions is only 75% to 85% of the total volume.

Biochemical Monitoring

1. Acid-base and electrolyte status, 2. Glucose levels, 3. Renal functions (BUN, Creatinine), 4. Liver functions (Bilirubin, enzymes) 5. Major mineral status (Calcium, Phosphorus, Magnesium) and 6. Serum triglycerides.

Haematologic Monitoring

Complete blood count, coagulation functions (prothrombin time).

Functional Monitoring

Sensorium, improvement in ventilatory muscle function.

Frequency of Monitoring

Each of the monitoring parameters listed above could be on a frequency that is hourly, daily or weekly basis on the degree and level of stability to be attained.

MISCELLANEOUS

Highly-Related Issues

Ethics

Philosophies about NS in seriously ill patients should be discussed with the patient's family. Ethics committees help to protect and guide the intensivist. Prolonging useful life is different from delaying death.

Team approach

For optimal, safe and cost-effective PN and EN, a well-trained team is necessary.

CURRENT STATUS AND PROBLEMS

Currently those involved in providing special oral, enteral (tube) and/or parenteral nutrition can have a good degree of satisfaction in achievements in nutrition support. However, this satisfaction be tempered by the recognition that particularly with regard to not only parenteral nutrition but also in some respects to enteral feeding, there are unresolved issues of varying degrees of clinical importance. Good survival outcomes, e.g.:

- In pregnant women who are dependent on long-term parenteral nutrition, there is improved outcome of the very low-birth infant.
- Improved nutritional status of patients with a variety of serious malabsorption states including long-term survival and a good quality of life for those with severe short-bowel syndromes.
- Improved survival and outcome of acutely ill patients with severe trauma, burns, and infections.

Providing NS to ICU patients, when indicated, is as important as haemodynamic, respiratory, and pharmacologic support. Delay in initiating and maintaining effective NS is lethal. No patient is 'too sick' to receive NS! However, appropriate protective randomised controlled trials (PRCTs) to evaluate the role of NS in the ICU is needed. Some NS (i.e. PNS) may actually have established harm. "Thy food shall be thy remedy" Hippocrates (400 BC) – May Be Wrong. It is what we think we know already that often prevents us from learning. Claude Bernard ...Miles to go before?! Success.

26.1 Poisoning—Basic Considerations and Epidemiology

NP Singh, Gurleen Kaur

INTRODUCTION

The past 3 to 4 decades have seen a remarkable change in incidence and type of poisoning. A number of new compounds have been added to the list of potentially poisonous materials. Poisoning is the fourth most common cause of mortality in rural India, with childhood poisoning constituting 2.1% of total paediatric admissions and 1.2% of total deaths in this population. Acute poisonings are on the rise in many countries and similar trends have been observed in India as well. In spite of the fact that acute poisoning cases are second only to road traffic accidents in numbers, this is often a neglected health problem compounded with the problem of difficult diagnosis in poisoning cases. It is important to realise that poisonings are largely preventable and majority of poisoning cases die within 1 to 6 hours of exposure to poison. Therefore, it is imperative to have a sound knowledge in the subject of poisoning. In simple terms, a 'poison' is any substance that produces toxic effects to the human body. Hence, even drug overdose will be treated as poisoning.

EPIDEMIOLOGY

The exact incidence of poisoning in India remains uncertain but 1 to 1.5 million cases occur every year, of which 50,000 succumb to it. There is an increasing trend of poisoning with increase in age up to the third decade following which it declines, peak incidence being in 20 to 30 years of age group and rare cases occurring after 65 years of age. Half of the poisonings in India are suicidal, followed by accidental poisonings which are about one-fourth in proportion and homicidal poisonings contribute much less. Both suicidal and homicidal cases of poisoning are more common in India than in the Western countries, because of the ease with which poisons can be obtained from any market. Males are affected more than the females and most victims are recorded from the medium to low socioeconomic group primarily from rural areas. Most cases are literate and married people outnumber unmarried cases. Aluminium phosphide is the commonest poisoning agent reported from rural areas while organophosphorous agents are the commonest reported from other areas. Therapeutic drugs are responsible for only a minor proportion followed by food poisoning cases. Among the paediatric population, nonmedicinal compounds are the largest contributors, of which kerosene alone is responsible for the majority of cases.

APPROACH

While dealing with a case of poisoning, it is important to consider the following important facts:

1. Identification of the poison
   a. From the history/circumstantial evidence
   b. Signs and symptoms of the case
2. Entertain alternative differential diagnosis
   a. Differentiate from illnesses which can mimic poisonings
3. Identify comorbidities
4. Offer treatment
   a. Stabilise patient's vitals
   b. Removal of unabsorbed poison
   c. Use of antidote
   d. Enhance removal of poison from body
   e. Supportive management
5. Offer psychiatric counselling, especially for suicidal cases

HISTORY AND EXAMINATION

A proper history may be elusive because these patients may not be conscious or cooperative. However, an attempt should be made to ascertain the nature of poison, the quantity consumed, mode of exposure, the time of exposure and if there was any vomiting subsequently, which resulted in spontaneous expulsion of the ingested poison. A clinician should always suspect poisoning if there is any sudden unexplained unpredictable illness in a preceding healthy individual, specially if he/she is young or in transit (at railway stations or bus stations, drugging of innocent passengers with stupefying agents is common). A history of recent consumption of an unknown drink/food item from an unverified source, depression or acute stress, presence of insecticide box or pill box near the patient; are suggestive of poisoning.

In cases of poisonings, medical management needs to be provided promptly, resuscitative measures may need to be instituted in comatose or unconscious patients (see chapter on Cardiopulmonary Resuscitation). The first assessment of the patient's clinical condition is very important since it provides the baseline which can be used for subsequent assessments and also outlines the need for instituting emergency measures. After assessment of sensorium and vital signs and need for their management, a quick but thorough physical examination is essential. Absence of any focal deficits and just depression of sensorium without any parasympathetic or sympathetic symptoms could result from a cerebral depressant/sedative. Pupillary signs and signs of cholinergic or anticholinergic stimulation may help aid the diagnosis and in the institution of proper management. Miosis is observed in poisonings with organophosphates/carbamates, narcotics, barbiturates, phenothiazines, clonidine, phencyclidine; while mydriasis is seen with atropine, LSD, MAO inhibitors, nicotine, amphetamines, anti-histamines, tricyclic antidepressants. Skin colour can also be helpful at times – a cherry-red colour seen in carbon monoxide poisoning and cyanosis in absence of hypoxia indicates methaemoglobinaemia. Perioral corrosive burns and intraoral ulcerations and congestion suggest attempts at corrosive ingestion.

Odour of the poison may be evident from the clothes or skin, and breath odour can be helpful in cases of ethanol or aluminium phosphide poisoning. Colour of the urine can indicate jaundice resulting from hepatic toxicity or black colour may result from intravascular haemolytic reactions.

MANAGEMENT

Apart from the routine investigations vomitus, urine, gastric lavage samples and suspected skin scrapings should be preserved for toxicological screening.

Removal of Unabsorbed Poison

It is important that whatever poison has not yet gained entry into the human body should be immediately removed. Clothes need to be removed in cases of organophosphorous poisonings, wherein the poison might have spilled on the clothes since these poisons can gain entry though the skin as well. In cases of poisoning with gas (carbonmonoxide poisoning), patient should be removed from the room and brought to fresh air. Skin and eyes should be thoroughly washed in cases of corrosive burns. Gastric lavage is one of the most effective methods to remove the unabsorbed ingested poison, if performed within 2 to 5 hours of ingestion, but is contraindicated in corrosive and kerosene poisonings. Induction of emesis is not advocated as it is not an effective method and, moreover, it can result in aspiration, induce convulsions and there exists a danger of the poison being pushed in to the small bowel from the stomach and getting easily absorbed.

Use of Antidotes

By definition, antidotes are agents which counteract the effects of poisons. Specific antidotes to all poisons are not known and hence nonspecific antidotes along with supportive therapy are provided in most cases. Activated charcoal acts mechanically by absorbing and retaining within its pores organic and also, to a less degree, mineral poisons. Activated charcoal 50 gm per dose can be repeated 4-hourly and can be given with a cathartic agent like sorbitol. Potassium permanganate, because of its oxidising properties, is a nonspecific chemical antidote and a dilute solution of 1:2000 is commonly used for gastric lavage in opium poisoning. Specific antidotes like atropine is a physiological antidote for organophosphorous insecticide poisoning, naloxone for morphine poisoning, BAL (Dimercaprol) for chelating arsenic or mercury, calcium sodium edentate for lead poisoning, Desferrioxamine for iron poisoning, D-penicillamine for other heavy metal poisonings (lead, gold, mercury and copper).

Enhance Removal of Poison from Body

Adequate hydration is one of the foremost steps since most toxins/poisons are excreted by the kidneys. Adequate hydration helps maintain the blood pressure which in turn maintains proper perfusion of the kidneys and also aids renal excretion of the poison. Overhydration should be avoided if patient has underlying heart disease, severe anaemia, incipient heart failure or pre-existing renal failure. Forced diuresis can be employed by using frusemide and/or mannitol infusions. Forced acid diuresis is useful for amphetamine poisoning, while alkaline diuresis is beneficial for aspirin and barbiturate poisoning. Urinary alkalinisation is done by administration of IV sodium bicarbonate (1 litre of a 1.26% solution over 3 hours). Intravenous potassium supplementation is necessary to ensure the production of an alkaline urine. Urinary acidification is achieved by giving ammonium chloride 4 gm every 2 hours through Ryle's tube.

Dialysis Support

Small molecules that are free in the plasma (i.e. not protein bound) are removed by haemodialysis by diffusion down a concentration gradient from the plasma to the dialysate. This way, toxins of molecular mass up to 2000 D can pass unhindered through all dialysis membranes; the cut-off for high-flux membranes is above 10,000 D. Clearance is enhanced by increasing the blood flow rate and also the ultrafiltration rate. Haemodialysis is, however, ineffective if the poisons or toxins are lipid-soluble or significantly protein-bound. Haemodialysis can be employed for several poisons like barbiturates, theophylline, lithium, bromides, salicylates, digitalis and methanol. Haemofiltration generates convective transport of solute through the membrane and allows high flux up to a molecular mass of 40,000 D. Since most poisons have molecular weights of less than 1,000 D, haemofiltration usually does not offer any particular advantage over haemodialysis but is occasionally required for large molecules like metal chelating complexes (desferrioxamine and sodium ethylenediamine tetraacetic acid) and aminoglycosides. Haemoperfusion is more suitable in scenarios of poisonings vis-a-vis haemodialysis since it does not depend upon the ability of poison to cross a selectively permeable membrane. Peritoneal dialysis is relatively inefficient compared to haemodialysis or haemofiltration as it achieves low mass transfer of solute and at a slower pace. However, it can be employed when haemodialysis is not rapidly available or is contraindicated.

Exchange transfusion also has a role for poisoning cases complicated by massive haemolysis, as in sodium chlorate poisoning, wherein it will remove not only the poison but also red cell fragments and free haemoglobin. It can also be employed for hydrogen sulphide poisoning which is complicated by methaemoglobinaemia and sulphaemoglobinaemia.

Supportive Management

In many cases of poisonings, the agent may not be discernible and often a specific antidote does not exist. In these circumstances, the mainstay of management is supportive care supplanted by prevention and prompt treatment of complications. Common complications which may need to be managed include pain, arrhythmias, hypotension, electrolyte disturbances, seizures, coma, respiratory failure, hepatic failure, and acute renal failure.

CONCLUSION

Poisoning is a major problem in India. It can be suicidal, homicidal or accidental. Early, aggressive and planned approach is important. Try to identify, detoxify (removal of unabsorbed poison, use of antidotes or by haemofiltration/haemodialysis) maintain vitals, provide effective CPR required and once improved psychological assessment and support is a must, specially in suicidal poisoning. Legal aspects must, be kept in mind.

26.2 Aluminium Phosphide Poisoning

SN Chugh

INTRODUCTION

Aluminium phosphide (AIP), a solid fumigant pesticide is widely used in India for grain preservation at homes and in warehouses. It protects the stored grain from pests, insects and rodents by liberating toxic phosphine (PH_3) gas after coming in contact with moisture. It is available in the form tablets, each weighing 3 g and packets, each weighing 10 g, packed in containers (**Figures 1A to C**). Each tablet/packet contains 56% of AIP and 44% of ammonium carbonate [$(NH_4)_2CO_3$] as active ingredients; is able to liberate PH_3 by one-third of its weight. Phosphine, being a gas, diffuses uniformly throughout the grains and the residues such as phosphite and hypophosphite of aluminium are left in the packet/grains which are nontoxic.

The poisoning is generally suicidal, rarely homicidal and occasionally accidental (children) and is common in younger age groups.

Figures 1A to C: Available packagings of celphos. (A) Tube containing tablets of celphos; (B) Small pack containing 10 packets of celphos weighing 10 g each, and (C) Large container having 50 packets of celphos weighing 10 g each.

MODE OF ACTION OF PHOSPHINE

Its toxic effects are due to the liberation of PH_3 in the stomach after ingestion of AIP. Inhalation toxicity (inhalation of PH_3) is uncommon and primarily involves lungs. The other gases liberated in addition to PH_3 include ammonia and CO_2 which provide an inert media for PH_3 to act:

$$AlP + 3HCl \rightarrow AlCl_3 + PH_3\uparrow$$
$$AlP + 3H_2O \text{ (moisture)} \rightarrow Al(OH)_3 + PH_3\uparrow$$
$$(NH_4)_2CO_3 + H_2O \rightarrow 2NH_3\uparrow + CO_2\uparrow + 2H_2O$$

The exact mode of action of PH_3 is not known. It has been claimed to inhibit cytochrome c oxidase, a respiratory chain enzyme, similar to cyanide. Some workers have claimed inhibition of mitochondrial catalase enzyme, extra-mitochondrial release of hydrogen peroxide (H_2O_2) and generation of oxygen free radicals by phosphine (PH_3). Free radicals seem to play a role in the initiation and propagation of cell damage, in addition to the direct toxic effects of phosphine.

CLINICAL TOXICITY

The toxic dose of oral AIP compound is 500 mg/70 kg in humans. Toxicity occurs either due to suicidal ingestion of AIP or inhalation of liberated PH_3 from fumigated grains. Phosphine is widely absorbed and distributed in the tissues. It is also known that AIP is absorbed as such and possibly deposited in liver leading to slow release of PH_3 which may be responsible for extended poisoning in humans.

The signs and symptoms of acute, moderate-to-severe ingestional poisoning appear within 45 minutes to one hour. The organs involved include gastrointestinal tract, heart, lungs, liver, kidneys and the brain. The clinical manifestations are depicted in **Table 1**.

Inhalational toxicity is invariably accidental; occurs in persons sleeping in warehouses where stored grains are fumigated with AIP. An exposure to high PH_3 concentration leads to shock or cardiovascular collapse but a lower concentration produces pulmonary oedema. However, the lower concentration (7.5 mg/m^3) may cause cough, dyspnoea and mild respiratory failure.

Table 1: Symptoms and Signs of Moderate-to-severe Aluminium Phosphide Poisoning

System	Common	Uncommon/Rare
Gastrointestinal tract	Nausea, vomiting, epigastric discomfort, retrosternal burning	Diarrhoea
Cardiovascular	Hypotension or shock tachycardia myocarditis arrhythmias	Bradycardia pericarditis congestive heart failure
Respiratory	Cough, dyspnoea, rhonchi, crackles, foul breath	Type 1 and type 2 respiratory failure
Hepatobiliary	—	Jaundice, hepatomegaly, raised transaminases, hepatic failure
Renal	—	Acute renal failure
Central nervous system	Anxiety, apprehension, irritability, disturbances in consciousness	Drowsiness and coma

INVESTIGATIONS

1. Complete haemogram
2. Blood biochemistry, e.g. urea, sugar, creatinine, transaminases, bilirubin, electrolytes, etc.
3. Electrocardiogram (ECG) for arrhythmias, myocarditis and conduction defects.
4. Chest radiograph (posteroanterior view) for acute respiratory distress syndrome (ARDS), aspiration pneumonia, etc.

5. Blood gas analysis for hypoxia and acidosis
6. Serum magnesium levels
7. Toxicologic screening, e.g. blood phosphine levels.

DIAGNOSIS

The clinical diagnosis of acute moderate-to-severe poisoning can be made from:

1. History of intake of fresh AIP compound
2. Decaying fish or garlic-like odour in breath
3. Evident clinical manifestations, cardiac arrhythmias and metabolic acidosis
4. The confirmation of diagnosis is done by positive qualitative silver nitrate test with gastric fluid or with breath (**Figure 2**) or blood phosphine levels.

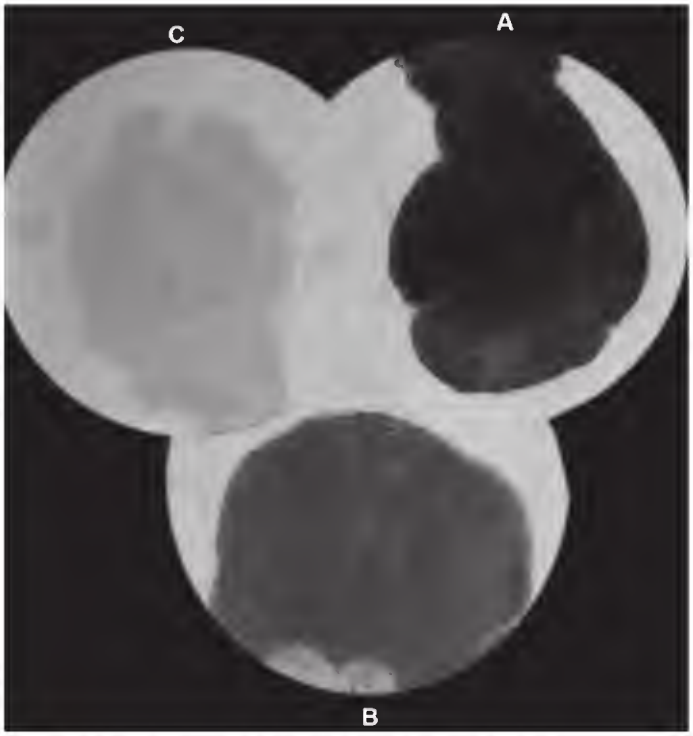

Figure 2: Qualitative silver nitrate ($AgNO_3$) impregnated (0.1 N) paper test in aluminium phosphide poisoning. Blackening indicates positivity; (A) positive with gastric lavage fluid; (B) positive with breath; and (C) a control for detection of H_2S.

Nil toxicity means ingestion of exposed compound (tablets kept out of containers or powder in open packets) which does not produce any systemic manifestation except local symptoms such as nausea, vomiting or retrosternal burning. Prognosis is excellent.

Mild ingestional toxicity is diagnosed by the history of taking a small dose of partially exposed compound (broken tablet/exposed packet/non-smelling tablet). There is a slight drop in blood pressure with nausea, vomiting, retrosternal burning or pain. Arrhythmias are occasional and metabolic acidosis is rare. $AgNO_3$ test is negative. Most of these patients survive.

All types of cardiac arrhythmias (brady- or tachy-arrhythmias) have been observed either alone or in combination with other ECG changes in 40% to 80% patients with moderate-to-severe poisoning. The ST segment elevation/depression due to acute myocarditis (**Figure 3**) is also observed commonly (30%). The conduction disturbances (sinoatrial, atrio-ventricular, bundle branch blocks, intra-ventricular conduction delay, etc) are least common, occurring in 5% to 10% patients.

There may be hypoxaemia (PaO_2 <60 mmHg) and metabolic acidosis (pH <7.1) in 75% to 80% cases. Magnesium levels have been found to be low or normal. Hypokalaemia or hypoglycaemia has been observed.

Sometimes, patients may not divulge the history of AIP ingestion. In such a situation, a high degree of suspicion combined with sudden onset of unexplained shock or cardiac arrhythmias and blood samples, if appear too dark to explain, form important clues to the diagnosis of this poisoning in younger patients.

MANAGEMENT

The early recognition and management is essential to reduce mortality. The main goal of therapy is to sustain life till PH_3 gets excreted.

Steps to Remove as well as to Retard PH_3 Absorption

Gastric lavage with $KMnO_4$ (1:10,000) or magnesium sulphate to inactivate or oxidise the unabsorbed poison. Slurry of activated charcoal (100 g) may be given to absorb PH_3.

Judicious use of antacids (60 mL/hour) to reduce gastric symptoms and to reduce PH_3 absorption. In addition, if needed H_2-blockers may be given as intravenous infusions.

Steps to Reduce Tissue Toxicity

There is no specific antidote to phosphine. Magnesium sulphate possesses membrane stablising properties and has been used in several studies from India. The effective dose schedule is to start with 1 g IV, then 1 g IV after one hour for 3 consecutive hours, then 1 g IV infusion after 4 to 6 hours for 3 to 5 days. It can reverse some arrhythmias and mortality is reduced.

Phosphine is a stable, partially water soluble gas and is excreted to some extent in the urine but is mainly excreted through breath; hence, adequate hydration and renal perfusion by IV fluids and low-dose dopamine 2 to 4 µg/kg/min must be maintained to allow its renal excretion. Diuretics are not useful in the presence of shock. Patients with severe poisoning are haemodynamically unstable but maintain a good urine output, hence, dialysis is usually not done. If acute renal failure develops and patient is haemodynamically stable, then dialysis may be useful.

Supportive Measures

The various supportive measures to manage complications are shown in **Table 2**.

MORTALITY

Mortality is highly variable (37% to 100%) depending on the factors such as dose of the fresh pesticide consumed, early vomiting, duration and severity of poisoning, severity of shock and its response to resuscitative measures, etc. The most common cause of death is acute cardiovascular collapse followed by the development of ARDS. Early vomiting is the single factor that improves mortality.

POSTMORTEM FINDINGS

Postmortem findings include the viscerae to be heavy, oedematous and emitting foul smell. The lungs show desquamated epithelium with alveoli thickened by haemolysed red blood cells and leucocytic infiltration around bronchioles.

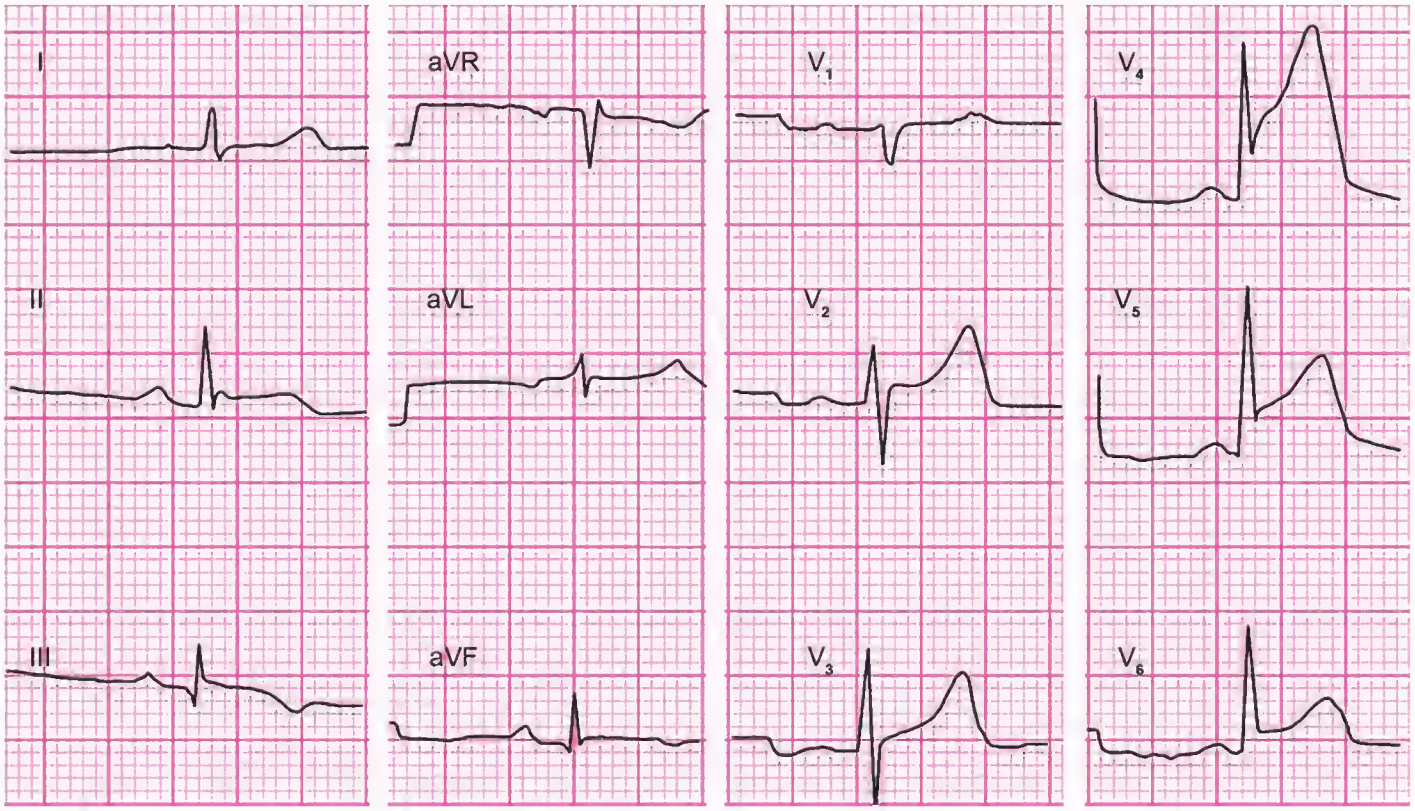

Figure 3: Myocarditis: The ECG shows: (i) Low voltage of QRS complexes in standard leads (I, II, III, aVR, aVL, aVF); (ii) Slight prolongation of QT (QTc) interval; and (iii) Elevation of ST segment with concavity upwards in leads II, III, aVF and V_1-V_6. Reciprocal ST depression in aVR is also seen.

Table 2: Treatment of Complications

Hypoxia	O_2 inhalation, patent airway (endotracheal intubation and assisted ventilation, if necessary). Monitor blood gases.
Shock	Intravenous (IV) fluids (2 to 3 litres, out of which 50% should be saline) to be given during first 3 to 6 hours guided by central venous pressure or pulmonary capillary wedge pressure. Monitor electrolytes. Blood pressures should be monitored and kept above 80 mm Hg. Low-dose of dopamine (2 to 4 µg/kg/min) and dobutamine (2.5 to 5 µg/kg/min) may be used in combination to maintain renal perfusion. IV hydrocortisone (200 to 400 mg) every 4 to 6 hours has been used to restore sensitivity to endogenous catecholamines.
Arrhythmias	Conventional antiarrhythmic drugs such as digoxin and xylocaine are ineffective. Others drugs being myocardial depressants are avoided but amiodarone has been used to combat fatal arrhythmias. Atropine has been found ineffective in bradyarrhythmias. $MgSO_4$ has also been found effective as a potent antiarrhythmic drug in the presence of hypoxia (anti-hypoxic effect), has been extensively used and found to be effective in certain arrhythmias.
Metabolic acidosis	IV sodium bicarbonate to keep the HCO_3^- levels around 18 to 20 mmol/L and pH >7.1. Dialysis is to be done if metabolic acidosis persists and patient is haemodynamically stable.
Acute respiratory distress syndrome (ARDS)/noncardiogenic pulmonary oedema	Remove the patient to open air and loosen the clothes around the neck. To achieve PaO_2 around 60% with lowest inspired fraction of O_2 (FiO_2), oxygen is delivered by simple face mask or face mask fitted with inspiratory reservoir bags at moderate flow rates (5 to 10 L/min of 100% O_2). Mechanical support is indicated if above measures fail. Positive end expiratory pressure therapy may be tried to lower FiO_2 below 0.6 provided patient is haemodynamically stable. Swan-Ganz catheter may be inserted for monitoring arterial and pulmonary wedge pressure, to measure cardiac output, fluid therapy, to monitor blood gas analysis and to guide diuretic therapy.
Hypoglycaemia	IV dextrose to combat hypoglycaemia which is reversible.

The liver shows congestion, oedema, areas of centrizonal necrosis and mild-to-moderate fatty infiltration. The heart shows congestion, oedema, fragmented fibres, focal areas of myocardial necrosis and leucocytic infiltration. The kidneys show congestion, oedema, necrosis and degenerative and regenerative activity of the tubules. The stomach and the intestines also show congestion, oedema and leucocytic infiltration with sloughing of mucosa.

26.3 Organophosphorous Poisoning

Surjit Singh

Organophosphorous (OP) compounds are a diverse group of chemicals comprising of either esters, amides or thiol derivatives of phosphoric acid principally used as insecticides in agriculture. They can be classified into low volatile compounds, e.g. chlorpyriphos, dimethoate, dichlorvos, methyl parathion, etc. used for agricultural purposes as insecticides or highly volatile nerve gases, e.g. sarin, tabun, etc. mainly used for chemical warfare. Acute OPs poisoning occurs mainly following ingestion with suicidal intent and less commonly following accidental exposure during agricultural spray.

PATHOPHYSIOLOGY

Organophosphates inhibit both plasma cholinesterase (PChE) and acetylcholinesterase (AChE), the later being present in red blood cells and tissues. The significance of inhibition of PChE is not clear. AChE is found at neuronal synapses in central nervous system (CNS) and peripheral nervous system and its main function is to hydrolyse acetylcholine (ACh). The bond between organophosphates and AChE changes with time and becomes irreversible when one of the alkyl radicals gets separated from OPs, the process being called as ageing. The time course of ageing depends on the molecular structure of the OP compounds. It is shorter for methoxy than ethoxy compounds. Once AChE has been inactivated, its inhibition leads to accumulation of ACh throughout the autonomic nervous system, somatic nervous system and the brain, resulting in overstimulation of the muscarinic and nicotinic receptors.

CLINICAL FEATURES

Following organophosphate poisoning (OPP), 3 well-defined neurological syndromes are recognised. These are cholinergic crisis, intermediate syndrome and delayed polyneuropathy. In addition, there are effects on other physiological systems such as CNS, cardiovascular system (CVS), pancreas, etc. which are also important.

CHOLINERGIC CRISIS

The initial cholinergic crisis is a medical emergency which may require intensive treatment. The crisis occurs as a result of accumulation of ACh at muscarinic and nicotinic sites. The excess ACh at these receptors leads to their initial stimulation and then eventual exhaustion. The accumulation of ACh at muscarinic sites leads to increased secretions leading to bronchorrhoea, salivation, sweating and tearing. There also occurs bronchospasm, vomiting, diarrhoea, the latter being due to increased gastrointestinal (GI) motility (**Table 1**). In eyes, miosis and blurred vision results. The accumulation at nicotinic sites results in muscle fasciculation's and flaccid paralysis. The accumulation in CNS leads to headache, giddiness, drowsiness and in severe poisoning coma. Death can occur as a result of respiratory failure which may be central, peripheral or both or following fatal cardiac arrhythmias. The cholinergic crisis can last from 24 to 72 hours.

Table 1: Clinical Features of Cholinergic Crisis

Muscarinic effects	
Broncho-pulmonary	Bronchospasm, bronchorrhoea, noncardiogenic pulmonary oedema
Gastrointestinal tract	Nausea, vomiting, diarrhoea, abdominal pain
Sweat glands	Excessive sweating
Salivary glands	Excessive salivation
Eyes	Miosis, blurred vision, lacrimation
Cardiovascular system effects	Bradycardia, occasionally tachycardia, arrhythmias, QT prolongation, hypotension, hypertension (rare)
Nicotinic effects	Fasciculation, muscle weakness
Central nervous system effects	Headache, giddiness, drowsiness, coma seizures

INTERMEDIATE SYNDROME

It was first termed as type II paralysis and subsequently renamed as intermediate syndrome (IMS). It occurs between the cholinergic syndrome and late onset peripheral neuropathy. It develops 12 to 96 hours after exposure and reflects a prolonged action of ACh on nicotinic receptors. The clinical features are muscular weakness in the ocular, neck, bulbar, proximal limb and respiratory muscles with occasional dystonic posturing (**Table 2**). The risk of mortality is due to respiratory depression as a result of muscle paralysis. IMS has been found to be associated more with certain OPC's, like diazinon, dimethoate, methyl parathion, methamidaphos, monocrotophos, fenthion and ethylparathion.

Table 2: Clinical Features of Type II Paralysis (Intermediate Syndrome) in Organophosphate Poisoning in 101 Patients in a Study by Wadia *et al.*

Inability to lift neck	87
Inability to sit up	99
Ophthalmoparesis	27
Slow eye movements	39
Facial weakness	52
Swallowing difficulty	14
Limb weakness (proximal >distal)	86
Areflexia	52
Respiratory failure	37
Death	33

DELAYED NEUROPATHY

Some organophosphates, particularly triorthocresyl phosphate (TOCP) and tricresyl phosphate (TCP) produce what is called delayed neuropathy. On ingestion, they do not produce significant cholinergic crisis but 7 to 20 days later lead to a pure motor axonal neuropathy with wrist and foot drop. It is probably due to depression of a different type of esterase (neuropathy target esterase) in the nervous system. This form of toxicity has

been seen occasionally in small epidemics in India due to adulteration of cooking oil with TOCP. However, with presently used organophosphates such as chlorpyriphos, it is uncommon.

LABORATORY DIAGNOSIS

The diagnosis can be made from history of ingestion or muco-cutaneus exposure, clinical features and laboratory evaluation of plasma cholinesterase (PChE) and red cell acetyl cholinesterase (Red Cell AchE) activity inhibition. The depressed cholinesterase activity confirms the diagnosis of OP poisoning and it continues to remain depressed for 4 to 7 weeks. Though red cell AChE is more specific, PChE assay is easy and more widely available.

Prolonged QTc interval, elevated ST segment, inverted T waves and prolonged PR interval are often observed electro-cardiographic (ECG) findings. *Torsade de pointes* and complete heart block have also been reported.

MANAGEMENT

The initial management involves maintaining a clear airway and intubation might be necessary in case of respiratory distress. Assessment of vitals should be done and undertake resuscitation if necessary. The rest of management includes removal of OPCs from skin and gastrointestinal tract, administration of activated charcoal, atropine or glycopyrrolate, oximes and some newer compounds in addition to ventilatory support which they may require.

Washing the skin with soap and water after removal of clothing is essential if there has been an accidental exposure, e.g. during agricultural spray. Care should be taken by health workers to protect themselves by using gloves, aprons, eye protection, etc., as they run the risk of getting poisoned by contact. In case of ingestion, emesis should not be induced as it can lead to complications like aspiration pneumonia, diarrhoea, paralytic ileus. There is no evidence at present that it helps in outcome and can lead to complications like lung aspiration, laryngeal spasm, oesophageal perforation and hypoxia. In India, as suicide is still an offence, gastric lavage is being carried-out routinely for medicolegal reasons to collect lavage sample. As it becomes necessary in our country, due to legal reasons, it should preferably be carried-out using wide bore nasogastric tube and smaller aliquots of water or normal saline with airway protection in obtunded patients. Both single dose and multiple dose activated charcoal have been administered after lavage. However, its benefit is not clear and complications include aspiration pneumonia, vomiting, diarrhoea, constipation, ileus, etc. A recent study suggests that if administered within one hour of ingestion, it may improve outcome. However, if patient needs resuscitation, removal should not be given priority and patient should be resuscitated first.

Atropine acts as physiological antidote as it antagonises the muscarinic receptor mediated actions of excessive acetyl choline. However, it has little effect at nicotinic sites. It blocks excessive tracheobronchial secretions, bronchoconstriction, salivation and bradycardia. Unlike glycopyrrolate which cannot cross blood brain barrier, it counteracts the effects of ACh in CNS. It has also been shown to enhance neuromuscular transmission and transmitter release possibly by acting on muscarinic presynaptic inhibitory receptors which are involved in the feed back mechanism of transmitter release. Though optimum dose is not known, the first doses are generally given as boluses followed by infusion if dose requirement is large. The initial dose is 2 mg intravenously repeated every 5 to 10 minutes until signs of atropinisation appear, i.e. pulse rate >80 beats/min, pupillary dilatation, drying of axillae and clear chest. After this it can be given as boluses or as infusion to maintain the atropinisation (0.02 to 0.08 mg/kg/min), the later being considered better with dose being titrated by clinical response.

Glycopyrronium bromide has been used in place of atropine. Its effects are similar to atropine but there is less CNS toxicity as compared to atropine as it does not cross blood brain barrier.

The use of oximes is controversial. Oximes reactivate the AChE by removing the phosphoryl group from inactivated enzymes. As ageing takes longer with diethyl compounds than with dimethyl compounds, it is likely that oximes may lead to better reactivation in the former. Pralidoxime is the oxime used worldwide. It occurs in two forms, i.e. pralidoxime chloride and mesylate, the latter being less effective. Its major effect is on the peripheral nervous system as it does not cross the blood brain barrier easily. Its main action is to effect recovery of neuromuscular transmission at nicotinic synapses. Complications of oximes include hypertension, cardiac dysrhythmias, headache, blurred vision, dizziness, etc. Obidoxime can lead to hepatic failure. A recent double-blind, randomised study from Sri Lanka has shown a higher mortality in the group treated with high-dose pralidoxime though in some previous studies a better outcome in patients given high-dose pralidoxime was observed. Thus, role of oximes is still controversial.

Diazepam is the standard treatment for organophosphorous induced seizures.

Mortality in OP Poisoning

The mortality in most large series is between 7% to 12%. Death is usually a result of respiratory paralysis. The other complications which can lead to fatality are asphyxia as a result of increased bronchial secretions and bronchoconstriction and rarely pulmonary oedema. Occasionally serious cardiac arrhythmias can lead to fatality. The mortality can be greatly reduced if patients are provided atropine and respiratory assistance in time.

NERVE GAS POISONING

Nerve gases used in warfare are organophosphates (soman, sarin, etc.). They are powerful irreversible inhibitors of ChE. In addition they phosphorylate other proteins and part of their toxicity may be due to this. The usual oximes are not effective in nerve agent poisoning.

CARBAMATES

Carbamate poisoning, e.g. Baygon poisoning (Propoxyfur) is increasingly being seen in urban areas in India. They are commonly used in households to kill cockroaches. They produce toxicity similar to that of OP poisoning. The management is similar except that oximes are contraindicated.

RECOMMENDED READINGS

26.4 Corrosive Poisoning

Rakesh Kochhar

The term corrosive poison encompasses alkaline and acidic agents which cause tissue destruction when they come in contact with mucous membranes. While Lye is the commonest ingested corrosive in the West, acidic agents are more often ingested in the developing world. Corrosive poisoning is often accidental in children, but in adults suicidal ingestion is common. Suicidal acid ingestion in the form of toilet cleaning agents has been one of the commonest form of corrosive poisoning for the last 3 decades.

CORROSIVE AGENTS (Table 1)

Caustic injury is usually produced by strong alkaline or acidic agents. Acid ingestion is common in India where hydrochloric acid and sulphuric acid are easily available as toilet cleaners. Commercially available liquid alkali, sodium hydroxide (e.g. Harpic) is the commonly ingested alkali in India. Laboratory workers (hydrochloric acid, nitric acid, sulphuric acid) and goldsmiths (aqua regia) ingest acids accidently. In recent years, button-cell battery ingestion in children is also being increasingly recognised.

Table 1: Common Corrosive Agents

Acidic Corrosives		
Total cleaners	:	Hydrochloric acid, Sulphuric acid
Antirust compounds	:	Hydrochloric acid, Oxalic acid
Soldering fluxes	:	Hydrochloric acid
Automobile battery fluid	:	Sulphuric acid
Slate cleaner	:	Hydrochloric acid
Alkaline Corrosives		
Drain cleaners	:	Sodium hydroxide
Surface cleaners	:	Ammonia, Phosphates
Laundry and dishwasher	:	Phosphates, Carbonates
Clinitest tablets	:	Sodium hydroxide
Industrial strength bleach	:	Sodium hydroxide, Calcium hypochlorite

The extent of injury following corrosive ingestion depends upon the nature of the corrosive agent ingested, its physical state, amount and concentration and the duration of contact with the mucosa. Acid solutions cause immediate pain which causes the person to spit the corrosive out. However, if the ingestion is intentional the corrosive is swallowed before the protective reflexes can be evoked. Severity of injury is also influenced by the physical state of the corrosive (solid or liquid). Soild crystalline agents (e.g. sodium hydroxide crystals, potassium permanganate crystals) tend to adhere to glossopharyngeal, palatal and upper oesophageal mucosa producing deep burns limited to the corresponding area. Liquid alkalis and acids, because of their easy deglutition and high specific gravity, pass rapidly through the oesophagus. Injury pattern also depends upon the postprandial state of the patients. If the stomach is full the agent is rapidly diluted and gastric mucosa is spared. When the stomach is full, the corrosive bolus flows rapidly from the gastro-oesophageal sphincter along the lesser curvature to the pyloric antrum where maximum damage occurs. It was earlier believed that alkalis bite the oesophagus due to liquefaction necrosis of the squamous epithelium, and lick the stomach due to dilution by its acidic contents. Acids were believed to spare the oesophagus and damage the stomach. However, we have shown that concentrated alkalis and acids, both cause similar damage to oesophagus as well as the stomach. Solid corrosives in powder form, like caustic soda, more often cause oropharyngeal burns while liquid corrosives damage the oesophagus and the stomach.

PATHOPHYSIOLOGY

Concentrated acids produce coagulative necrosis with a protective eschar. This coagulum tends to limit the penetration into deeper muscular coats. But sloughing and expulsion of large areas of the surface lining of the stomach and oesophagus with secondary infection and perforation may pose problems. In severe cases associated with perforation, the resulting peritonitis or mediastinitis can lead septicaemia and its sequelae. Apart from oesophageal injury causing strictures because of antral pooling of the caustic agent, some patients may develop pyloric obstruction or antral stenosis or hourglass deformity. These can develop within weeks to months after ingestion of the agent.

Alkaline caustic agents rapidly penetrate into tissues and produce injury by liquefaction necrosis with intense inflammation and saponification of mucous membrane, submucosa and muscularis mucosa within 2 to 3 days of contact. Mucosal sloughing occurs 4 to 7 days after injury. Stricture formation starts by 3rd week, although it can occur for the first time several years later.

CLINICAL PRESENTATION

Acute Phase (1 to 10 days)

This is characterised by acute symptoms like pain, dysphagia, haematemesis, etc. Laryngeal oedema can cause hoarseness of voice and stridor. Aspiration of the caustic agents into airways can cause chemical bronchitis. Full thickness necrosis can produce perforation leading to mediastinitis, pleural effusion, empyema or peritonitis. Septicaemic shock is a common cause of death in acute phase.

Subacute Phase (11 to 16 days)

There is transient decrease in above mentioned symptoms.

Chronic Phase (28 days to months)

Characterised by oesophageal strictures causing dysphagia, and gastric stenosis causing gastric outlet obstruction.

ENDOSCOPIC FINDINGS AND CORRELATION WITH OUTCOME

Symptoms and signs are poor indicators of degree and extent of damage to the gastrointestinal tract. Radiological studies are also not sensitive. The best method to stratify patients with

acute corrosive ingestion is upper gastroduodenal endoscopy whose safety has been well established. Flexible endoscopy can be performed safely at any time from 6 to 96 hours of ingestion, provided the patient is stable and there is no evidence of perforation. However, it should be avoided in the sub-acute phase (5 to 15 days) after corrosive intake when the tissues slough and there is increased danger of perforation. On the basis of endoscopic findings, corrosive burns have been classified into grades 0, 1, 2 and 3 (**Table 2**). Most perforations and fatalities in the acute phase occur in patients with grade 3b injury, while strictures develop in patients with grade 2b or worse injury. Therefore, such patients need to be kept under close supervision.

Table 2: Endoscopic Classification of Corrosive Burns

Grade 0	Normal examination
Grade 1	Oedema, hyperaemia of the mucosa
Grade 2a	Friability, haemorrhage, erosions, blisters, whitish membrane exudate and superficial ulceration
Grade 2b	Grade 2a + deep discrete or circumferential ulceration
Grade 3a	Multiple ulcerations and small, scattered, nonconfluent areas of necrosis (area of brown-black or greyish discolouration)
Grade 3b	Extensive necrosis, confluent necrosis

MANAGEMENT

Acute Injury

The management of acute corrosive injury consists of recognition and treatment of acute complications and treatment of sequelae. Early treatment includes maintaining the patient nil per orally, intravenous fluids, airway maintenance and supportive treatment. After resuscitation, acute complications like perforation and peritonitis should be ruled out by radiograph chest, radiograph abdomen and a radiological soluble contrast study, if indicated. Upper gastrointestinal endoscopy should be done to evaluate the severity of burn. Airway management may require tracheostomy. Treatment of infections is an essential part of early management.

There is sufficient evidence that gastric lavage, use of emetics, or purging agents are contraindicated, since these cause more harm than any good. Neutralisation of the corrosive agents with weak acid or alkali used to be done in the past. But its efficacy could never be proved probably due to the rapid action of acids or alkalies. Dilution with water is also not useful as it may cause more harm by liberation of heat. Hence, neutralisation is contraindicated.

Antibiotics are given only when patients have symptoms and signs of secondary infection. Steroids have no role in prevention of late sequelae. The only indication of using steroids could be laryngeal oedema. Parenteral steroids may lead to systemic infection in a bed-ridden patient. Indications for surgery include perforation of oesophagus or stomach, massive upper gastrointestinal bleed and full thickness burns of oesophagus or stomach with charring.

Patients are unable to have normal diet in the first few weeks after acute corrosive ingestion due to mucosal oedema and ulceration. Later development of cicatrisation in the oesophagus and stomach precludes normal feeding. Hence for 6 to 8 weeks, patients require nutritional support with total parenteral nutrition or feeding jejunostomy. The latter is preferred in India. Recently, endoscopically placed naso-jejunal tubes are being used for maintaining enteral nutrition in these patients.

Chronic Phase

Late sequelae include oesophageal and/or gastric cicatrisation. It is essential to do a barium study to assess the site, extent and nature of oesophageal and gastric stenosis (**Figures 1 to 4**). Generally, endoscopic treatment is offered 6 to 8 weeks later, once re-epithelialisation has taken place.

1. Oesophageal strictures are often long, tortuous, multiple and very tight (**Figures 1 and 2**). They require repeated dilatation endoscopically with bougies or balloons and recurrences are frequent. Corrosive oesophageal strictures

Figure 1: Barium swallow showing a long stricture involving middle and lower thirds of oesophagus in a patient with sulphuric acid ingestion (Anteroposterior view, left; left oblique view, right).

Figure 2: Barium swallow showing a single short mid-oesophageal stricture in a patient with toilet cleaner ingestion.

are difficult to dilate but over three-fourths of them respond to endoscopic dilatation. It has been shown that combining intralesional steroid injections with dilatation is very rewarding in difficult strictures. Recently, self expanding plastic stents have also been used in such patients with good results. Patients who cannot be dilated or have frequent recurrences are subjected to esophageal bypass using a jejunal or colonic loop or gastric pull up.

2. Gastric cicatrisation leads to pyloric and/or antral stenosis (**Figures 3 and 4**), clinically presenting as recurrent vomiting. Such patients often require surgery with antrectomy or partial gastrectomy. Some patients have linitus-plastica like deformity involving a large part of the stomach requiring subtotal or total gastrectomy. Recently, endoscopic balloon dilatation has been used successfully to treat pyloric stenosis due to corrosive injury.
3. Oesophageal carcinoma: Risk is estimated to be 1,000-3,000-folds and it usually occurs 20 to 30 years after an acute injury.

Figure 3: Barium meal study showing a dilated stomach with total obstruction at pylorus in a patient with hydrochloric acid ingestion.

Figure 4: Barium meal study showing two strictures, one at body-antrum junction and another at pylorus in a patient with sodium hydroxide ingestion.

SUMMARY

In India, acid ingestion is more common than alkali ingestion. Strong acids and alkalis cause equal injury to oesophagus and stomach. Management of acute injury involves resuscitation, maintenance of airways and supportive care. At 6 to 8 weeks barium studies are done to assess for chronic sequelae. Endoscopic dilatation of oesophageal strictures and localised pyloric stenosis form the first line of treatment. Surgical treatment is indicated for long oesophageal strictures, in patients who fail to respond to dilatation and those with long segment of gastric stenosis.

26.5 Alcohol Poisoning

Pritam Gupta, Ankur Gupta

The most commonly used alcohol is ethyl alcohol (ethanol). Unlike ethanol, methyl alcohol (methanol) is extremely toxic. Two other alcohols commonly used (though not as much as methanol and ethanol) are propyl alcohol and butyl alcohol. Prompt recognition and treatment of patients intoxicated with these substances can reduce the morbidity and mortality associated with these alcohols.

ACUTE ALCOHOL POISONING

The term alcohol in common use refers to ethyl alcohol. At low doses, alcohol can have some beneficial effects such as decreased rate of myocardial infarction, stroke, gallstones and possibly vascular and Alzheimer's disease. However, if taken in large amounts, it can be toxic as well as fatal. The characteristic flavour of alcoholic beverages is due to organic compounds called congeners, such as propyl alcohol, octyl alcohol, glycerine, aldehyde, esters and certain acids. The total content of congeners rarely exceeds half per cent.

Metabolism

Twenty per cent of alcohol is absorbed from oral cavity, oesophagus, stomach and the rest from small intestine. About 60% of diluted alcohol is absorbed within half an hour if taken on an empty stomach. The rate of absorption is increased by rapid gastric emptying, absence of fats and proteins, optimal dilution of 20% by volume and carbonation. Five per cent of alcohol is excreted in breath and another 5% through urine. The peculiar odour of alcohol is due to excretion of alcohol from skin glands. Ninety per cent of alcohol is metabolised in the liver. Alcohol is oxidised into acetaldehyde by alcohol dehydrogenase (ADH). Acetaldehyde in turn gets converted to acetate and fatty acids by aldehyde dehydrogenase and acetyl-CoA. Finally, acetate enters the general pool and oxidises into carbon dioxide (CO_2) and water (H_2O) through the Kreb's cycle pathway.

Clinical Manifestations

Ethanol depresses primarily the reticular activating system. In lower concentrations, it causes depression of more specialised and sensitive cells of the cerebral cortex (centers regulating conduct, judgement and self-criticism), with release of their inhibitory tone and leads to unrestrained behaviour. Increasing concentration progressively depresses brain function. Finally, the vital centres in the midbrain and medulla are depressed, which may cause cardiorespiratory failure and death. It also causes generalised vasodilatation, especially in the skin. It is hypnotic and diaphoretic. The toxic effects of alcohol depend upon its concentration in the blood (**Table 1**). The clinical manifestations can be classified in 3 stages:

1. Stage of excitement
2. Stage of incoordination
3. Stage of narcosis

Table 1: Systemic Effects of Alcohol

Blood Alcohol Concentration	Effects
0% to 50 mg%	No significant effect or mild euphoria
50% to 100 mg%	Decreased inhibitions and attention span, increased self confidence, slurring, alteration of judgement, nystagmus
100% to 150 mg%	Mental confusion, emotional instability, ataxia, impaired memory, sleepiness, slowed reaction time
150% to 300 mg%	Loss of coordination, drowsiness, exaggeration of emotions, dizziness, disorientation, thickened speech
300% to 400 mg%	Stupor, marked decrease in response to stimuli, marked incoordination, possibly coma
400 mg% and above	Anaesthesia, depression of responses, respiratory failure, deep coma, death

Cause of Death

In alcohol intoxication, death may be due to the depressive effects on brainstem respiratory centre or due to aspiration of vomitus. Deaths due to acute overdose of alcohol are not as common as due to the chronic effects of alcohol.

Differential Diagnosis

The differential diagnosis of acute alcohol intoxication includes all causes of depressed levels of consciousness such as infections of brain, head injury, intracerebral haemorrhage, brain tumours and other metabolic conditions affecting the brain like hypoglycaemia, hyponatraemia, hepatic encephalopathy, uraemia or drug overdoses.

Management of Acute Alcohol Intoxication

Unabsorbed ethanol may be removed by gastric lavage. Adequate ventilation with maintenance of airway is important in a comatose patient. Sodium bicarbonate may be administered to alkalinise the urine. Hypoglycaemia is common and should be corrected with dextrose infusion along with simultaneous administration of 100 mg of thiamine parenterally. In a life-threatening emergency haemodialysis may be done to lower ethanol levels rapidly.

METHYL ALCOHOL POISONING

Methanol is a common ingredient in antifreeze, paints and solvents. It is also used in photocopying fluid, shellacs, and windshield-washing fluids. Poisoning usually follows ingestion of contaminated alcohol beverages or 'methylated spirits'. Intoxication in industrial settings follows absorption across the skin or lung.

Methanol is primarily metabolised in the liver via alcohol dehydrogenase into formaldehyde which is subsequently

metabolised via aldehyde dehydrogenase into formic acid, which is detoxified ultimately to folic acid, folinic acid, CO_2 and H_2O. Formic acid is responsible for the majority of the toxicity associated with methanol. Without competition for alcohol dehydrogenase, methanol undergoes zero-order metabolism. Once methanol experiences competitive inhibition from ethanol or fomepizole, the metabolism changes to first-order. In this latter scenario, the excretion half-life ranges from 22 to 87 hours.

Clinical Picture

It causes early temporary central nervous system (CNS) depression followed by a latent period lasting 6 to 24 hours before the development of metabolic acidosis and visual symptoms. Significant ingestion causes nausea, vomiting and abdominal pain. Its effects on the CNS resemble those of ethyl alcohol, although in low doses it does not have a euphoric effect. Visual symptoms present as falling visual acuity and photophobia. Specifically, vision is often described as a 'snow field', though a variety of visual complaints including blindness may be verbalised. Early signs include optic disc hyperaemia and decreased pupillary light reflex. Ingestion of only 10 mL can cause blindness and 30 mL can be fatal. Arterial pH seems to correlate best with formate levels and pH (< 7.2 is a severe intoxication).

Up to two-thirds of patients have raised serum amylase levels. Autopsy reveals haemorrhagic pancreatitis. Seizures are seen in severe intoxication. Computed tomography usually shows cerebral oedema or even necrosis in the basal ganglia (a Parkinsonian-like state is sometimes seen with recovery).

Serum methanol levels should be obtained when this diagnosis is suspected. Both the osmolal and anion gap should be obtained in addition to liver function tests, renal function tests and plasma glucose levels.

Management

Ipecac/gastric lavage is useful only if patient presents within 2 hours of ingestion. Activated charcoal is not indicated. Seizures should be best treated with phenytoin since this will have less of a CNS depressant effect than diazepam. Folinic acid should be administered at a dose of 1 mg/kg, with a maximal dose of 50 mg. It should be repeated every 4 hours. If folinic acid is not immediately available, folic acid can be substituted at the same dose. Metabolic acidosis should be treated with sodium bicarbonate.

Specific antidotes—ethanol or fomepizole should be used to prevent formation of formic acid (**Table 2**). Haemodialysis should be considered in certain situations (**Table 3**). The guidelines for the use of ethanol and fomepizole have been summarised in **Tables 4 and 5**, respectively.

Table 2: Indications for Treatment of Ethylene Glycol or Methanol Poisoning with Ethanol or Fomepizole

Documented plasma levels >20 mg/dL or
Recent history of ingestion and osmolal gap >10 mmol/kg
Strong clinical suspicion and at least 2 of the following:
pH <7.3
HCO_3^- <20 mmol/L
Osmolal gap >10 mmol/kg
Urinary oxalate crystals (in case of ethylene glycol) or visual signs/symptoms (in case of methanol)

Table 3: Indications for Haemodialysis in Ethylene Glycol or Methanol Poisoning

pH <7.3
Acute renal failure
Visual signs/symptoms
Deteriorating vitals despite intensive supportive care
Documented plasma levels >50 mg/dL

ETHYLENE GLYCOL

Ethylene glycol is an odourless, colourless, sweet-tasting liquid, which is used in many manufacturing processes. It is probably most commonly used as an antifreeze. It is absorbed rapidly from the gastrointestinal tract. Ethylene glycol itself is nontoxic, but it does get metabolised into toxic compounds. Ethylene glycol is oxidised via alcohol dehydrogenase into glycoaldehyde which subsequently undergoes metabolism via aldehyde dehydrogenase into glycolic acid. The conversion of glycolic acid to glyoxylic acid is slower and is the rate-limiting step in the metabolism of ethylene glycol. Glyoxylic acid is subsequently metabolised into several different products, including oxalic acid (oxalate), glycine, and alpha-hydroxy-beta-ketoadipate.

The majority of the metabolic acidosis occurs from glycolic acid. One form of morbidity occurs when oxalate combines with calcium to form calcium oxalate crystals, which accumulates in the proximal renal tubules, thereby inducing renal failure. Hypocalcaemia can ensue and cause coma, seizures, and dysrhythmias. Autopsy studies have confirmed that calcium oxalate crystals are deposited not only in the kidneys, but in many organs, including the brain, heart, and lungs.

Clinical Picture

Clinical presentation can be described in the following four stages:

1. The first stage, called the *neurologic phase*, can occur in less than 1 hour after ingestion and lasts up to 12 hours. During this stage, the patient appears inebriated. The patient may not have any other significant findings during this stage. Occasionally, hypocalcaemia can occur at this point and induce muscle spasms and abnormal reflexes.
2. The second stage, which occurs between 12 and 24 hours after ingestion, is referred to as the *cardiopulmonary stage*. During this stage, the patient frequently develops mild tachycardia and hypertension. Acute respiratory distress syndrome (ARDS) can also occur. These findings are believed to result from calcium oxalate crystal deposition in the lung parenchyma and myocardium. Significant hypocalcaemia can occur at this stage, with QT prolongation and associated arrhythmias. Hyperventilation may occur as metabolic acidosis progresses.
3. The third stage, also called the *renal stage*, typically starts after 24 hours. During this stage, flank pain and acute renal failure can occur.
4. The fourth stage is characterised by delayed neurological sequelae that occur 6 to 15 days after the original insult. Patients present with hyper-reflexia, ataxia, facial nerve palsy and other cranial nerve abnormalities.

Management

If presenting within a few hours of ingestion, gastric lavage is indicated. Commercial 'anti-freeze' often contains fluorescein which is easily detected with a UV light source (also detectable in urine). Microscopic evaluation of a fresh urine sample looking for the needle-shaped crystals of calcium oxalate monohydrate is pathognomonic.

Ethanol and fomepizole are specific antidotes and should be used as indicated in **Tables 2, 4 and 5**. Haemodialysis may be required in certain circumstances (**Table 3**).

Table 4: Guidelines for the Use of Ethanol in the Treatment of Ethylene Glycol or Methanol Poisoning

Loading dose: 0.6 g/kg IV 10% ethanol in 5% dextrose water or 43% of oral solution

Maintenance dose

- In alcoholic patients—154 mg/kg per hour
- In nonalcoholic patients—66 mg/kg per hour
- Double the dose during haemodialysis
- Double the dose if given orally with charcoal

Continue until ethylene glycol or methanol concentrations are <20 mg/dL and patient is asymptomatic with a normal pH

Table 5: Guidelines for the Use of Fomepizole in the Treatment of Ethylene Glycol or Methanol Poisoning

Loading dose: 15 mg/kg IV in 100 mL 0.9% saline over 1 hour

Maintenance dose: 10 mg/kg every 12 hours for 4 doses, then 15 mg/kg every 12 hours.

Continue until ethylene glycol or methanol concentrations are <20 mg/dL and patient is asymptomatic with a normal pH

SOME MEDICOLEGAL PITFALLS

1. Patients with alcohol intoxication should be evaluated for coexisting injuries. A common error is to assume that a patient with altered mental status is simply intoxicated without adequate consideration of other possible causes of an altered mental status.
2. Hypoglycaemia should always be sought, particularly in the setting of an altered mental status because it can occur both as a result of intoxication with alcohol and as a result of treatment with ethanol after toxic alcohol ingestion. At-risk populations include children, chronic alcoholics, and others whose glycogen stores are depleted such as malnourished patients.
3. Additional pitfalls include assuming that intoxication is due to simply ethanol without adequate consideration of the possible presence of a toxic alcohol, either exclusively or as a coingestant.
4. Patients who have accidentally ingested a mouthful of methanol or ethylene glycol can ingest enough to be at risk of developing significant toxicity.
5. Another pitfall is to assume that the absence of an anion gap rules out the possibility of toxic alcohol poisoning. This is especially true early in the course when a patient appears inebriated without other symptoms and before significant metabolism has occurred so that an anion gap has not yet developed.
6. Not considering the use of haemodialysis, particularly in the presence of metabolic abnormalities, is another potential pitfall. Consultation with a Nephrologist and/or Toxicologist may be of assistance.
7. Failure to initiate treatment while awaiting laboratory tests to confirm the presence of a toxic alcohol is another common source of medical error.

26.6 Plant Poisoning

DKS Subrahmanyam

INTRODUCTION

Plant poisoning in humans is a well known phenomenon, especially in semi-urban and rural India. It occurs following ingestion of any of the various parts of the plant, viz. fruits, seeds, flowers, leaves, stem and root, as in most situations all parts of the plant can be poisonous. The nature of the plant poisoning is influenced by regional practices, and hence, varies to some extent in various parts of our country, though oleander and abrus poisoning are seen all over. There appears to be a seasonal influence on the severity of the poisoning besides quantity and mode of ingestion. Plant poisoning can occur from contact, ingestion and rarely by inhalation. Most of the cases in adults are suicidal, less commonly accidental or homicidal. The following are the commonly encountered acute and at times fatal plant poisoning (in adults) in our country.

- Yellow oleander
- *Abrus precatorius*
- *Datura*
- Castor seed
- Aconite
- *Cleistanthus collinus*
- Indian hemp
- *Cerbera odollam*
- Nux vomica

SALIENT FEATURES

1. All parts of most plants are usually poisonous, though specific parts are used
2. Life-threatening poisoning occurs by ingestion
3. The severity of the toxicity is influenced by the time of the year (season effect)
4. The toxic dose is very unpredictable
5. Antidote is not available
6. Stomach wash and activated charcoal is indicated for all
7. There is an increased tendency to accidental poisoning, though in most, it is suicidal
8. Mortality is low
9. Good supportive care is the sheet anchor for treatment

CLASSIFICATION

Poisonous plants can be classified based on the chemical nature of the toxin, the mechanism of action of the toxin or the predominant system of the body involved. To the healthcare provider and recipient, classification based on the body system involvement is most useful and is as follows:

1. Gastrointestinal: *Abrus precatorius*, *Ricinus communis*, *Jatropha curcas*
2. Cardiovascular: Yellow oleander, white oleander, *Cerbera odollam*, aconite
3. Central nervous system (CNS): *Datura, Atropa belladonna*, *Strychnos nux-vomica*, Indian hemp (kidney)
4. Nephrotoxic: Aloe
5. Haemotoxic: *Gingko biloba*, fava beans
6. Hepatotoxic: Liquorice
7. Dermatological/contact poisons: Poison ivy, capsicum
8. Miscellaneous: *Cleistanthus collinus*, neem

Commonly encountered plant poisoning limited to their acute presentation following oral ingestion are described below.

YELLOW OLEANDER POISONING

Cerbera thevetia, commonly known as yellow oleander, is a shrub with green long lanceolate leaves, bell-shaped yellow flowers and a green fruit with two pale yellow seeds (**Figure 1**). Poisoning occurs following ingestion of the seeds or the crushed/chewed fruit. The number of seeds needed to cause significant poisoning is very variable. The active principles are thevetin, thevetoxin, cerebrin and nerifolin. These are all digitalis-like glycosides. As is with digitalis, toxicity occurs due to inhibition of Na^+/K^+ ATPase on cell membranes.

Patients may be asymptomatic even after ingestion of a large number of seeds. Symptomatic patients present most commonly with various cardiac arrhythmias including sinus bradycardia, various sino-atrial (SA) nodal disturbances (sinus pause, sinus arrest), atrio-ventricular (AV) nodal disturbances (first, second and third degree blocks), combined SA and AV nodal disturbances and ectopic rhythms. Tachyarrhythmia is uncommon. Other symptoms include nausea, vomiting, diarrhoea, pain abdomen and less commonly dry throat, oral paraesthesias, refractory hypotension and altered sensorium/delirium.

Blood biochemistry study may uncommonly show hyperkalaemia (because of shift from intracellular compartment)

Figure 1: Yellow oleander poisoning.

otherwise it is unremarkable. Electrocardiogram is essential to demonstrate the various arrhythmias for the management.

Management includes stomach wash using a wide bore tube. Activated charcoal 50 g is used as single dose and repeated if required. Cardiac arrhythmias of the SA nodal and AV nodal disturbances are best managed by temporary venous pacing. Sinus bradycardia can be managed with atropine injections at regular intervals or isoprenaline but with close monitoring. Tachyarrhythmias are treated with intravenous lidocaine. The role of intravenous magnesium in such situations is not well-defined. Hypotension is poorly responsive to routine measures. Serious poisoning can be treated with digoxin specific antibody fragments (Fab digoxin) 1,200 mg single intravenous dose. Hyperkalaemia rarely requires treatment and is best managed, if necessary, with intravenous dextrose and insulin. Intravenous calcium is to be avoided. Mortality in yellow oleander poisoning is 3% to 4%.

ABRUS PRECATORIUS POISONING

Abrus precatorius is a climbing plant with seeds that are scarlet red in colour with a black spot at one end. It is also called rosary pea, jequirity bean, rati, etc. Poisoning results from consumption of the seeds either crushed or chewed or made into a paste but not when consumed as a whole intact seed and rarely by inhalation when the active moiety is used as chemical warfare agent. It is usually ingested with suicidal intent. The toxic principle is abrin which is a toxalbumin or toxic protein with two chains namely A and B. The A chain has 256 residues and is the toxic component. It binds to 60S rRNA and inactivates it thereby preventing protein synthesis and causing cell damage. The B chain has 268 residues and is bound to the A chain by a disulphide bond at position cys 8 with cys 247 of A chain. The B chain binds to the cell surface receptor and facilitates the entry of the molecule into the cytoplasm. Abrin is a highly toxic chemical, only 0.1 to 1 mg/kg being sufficient to cause death.

Clinical manifestations are commonly of gastrointestinal origin and include nausea, vomiting, pain abdomen, diarrhoea which later turns bloody. Patient may later develop hypotension and shock. Acute renal failure, hepatotoxicity, intravascular haemolysis, altered sensorium and seizures can also occur. The toxin because of its nature of action can cause tissue oedema and vascular leakage/capillary leak syndrome.

Laboratory abnormalities include leucocytosis and other blood biochemical changes depending on the organ involvement.

Management includes gastric lavage, activated charcoal (50 g), and supportive care. Specific antidote is not available. There are reports of using intravenous methylprednisolone and mannitol for CNS toxicity. Seizures are controlled with diazepam, initial 10 to 20 mg (5 mg/min) followed by 3 mg/min continuous infusion over 24 hours. Alternatively phenytoin can also be used.

CASTOR SEED POISONING

Ricinus communis (castor) is so called as it resembles the common tick. This, like abrus, is an ornamental bean. The active principle is ricin, a glycoprotein also called RIP2 (ribosomal inhibitory protein 2), like abrin as it contains two chains A and B unlike RIP1 which is ubiquitous in the plant kingdom and which contains only the A chain. The mechanism of action, clinical features and treatment is the same as abrus. Mortality with castor seed poisoning is around 8%.

DATURA POISONING

The plant (*Datura fastuosa*) grows widely all over India. The flowers are bell-shaped, white or black/deep purple in colour. The fruit is green with spiny surface and contains capsicum (chilly) like seeds. Poisoning commonly results from ingestion of the seeds or the fruit (chewed/crushed). The active principles are hyoscine and hyoscyamine which have anticholinergic action.

A commonly and oft quoted rhyme to describe the clinical features of *datura* poisoning is: *'dry as bone, hot as a hare, red as beet, blind as a bat and mad as a hen'.*

Clinical features include bitter taste, vomiting, dry mouth and throat (dry as bone) with intense thirst and at the same time difficulty in swallowing and burning pain in the abdomen. On examination, patient feels hot/febrile with dry skin and rapid pulse. Body temperature may be as high as 40°C to 42 °C (hot as a hare). Face is flushed with suffused conjunctivae (red as beet). Neurological features include giddiness, dilated pupils with photophobia, diplopia loss of accommodation for near vision and near blindness (blind as bat). Unsteadiness with inability to stand/walk, confusion, agitative, violent, noisy, restlessness with tendency to runaway (mad as a hen) or silent muttering delirium, visual and auditory hallucinations with tendency to grasp imaginary objects or picking up bed clothes or pulling imaginary threads from finger tips (carphologia), spontaneous laughing/crying. This delirium phase lasts a few hours after which deep sleep supervenes following which he awakens with headache, vomiting, blurred vision, vertigo. This may last a few days followed by complete recovery. In fatal cases, patients pass into deep coma with hypotension/shock, respiratory depression, convulsions and death.

Management includes stomach wash (avoid in unconscious or violent individual), activated charcoal (50 g) with magnesium sulphate 30 g as cathartic every 4 to 6 hours till stools turn black. Supportive care includes intravenous diazepam for seizures, tepid sponging for hyperthermia, cool, calm and dark room if patient is agitated and intravenous physostigmine 0.5 to 2.0 mg in extreme situations.

ACONITE POISONING

Popularly known as 'monk's hood', its botanical name is *Aconitum napellus*. All parts of the plant are poisonous but the root is mainly used. It is more common in Eastern India. Poisoning results from ingestion either accidentally (mistaken for other edible roots) or taken in drink or food with homicidal or suicidal intent. The active principles are aconitine, mesaconitine, picraconitine, napelline, aconine, hypaconitine and other alkaloids. It acts on the voltage gated sodium channels keeping them in a persistent open state. These channels are predominantly in the heart, nerves and muscles which explains the symptomatology. In the heart it causes increased triggered activity and arrhythmogenicity, in the nerves it blocks neuromuscular transmission, in the CNS it acts on the ventromedial nucleus of the hypothalamus and causes hypotension and bradycardia. It also causes vigorous contractions of the ileum through increased release of acetylcholine from postganglionic cholinergic nerves.

Clinical features relate to the gastrointestinal, cardiovascular and neurological systems. Following ingestion patient complains of severe burning and tingling sensation in the lips, tongue, mouth,

throat and later numbness and anaesthesia of these parts. Nausea, vomiting, pain abdomen and less commonly diarrhoea ensue. Tingling and formication (sensation of ants crawling under the skin) all over the body, motor weakness, alternate dilatation and constriction of pupils (hippus) with visual impairment and vertigo are the neurological features. The cardiovascular features include chest pain, bradycardia or tachycardia, arrhythmias like ventricular ectopics, ventricular tachycardia and fibrillation, hypotension and shock. Death is mainly due to the refractory ventricular arrhythmias. Consciousness is usually retained till the end.

Treatment includes stomach wash, activated charcoal and supportive therapy. Supportive therapy includes inotropic therapy for hypotension, amiodarone, flecainide or even cardiopulmonary bypass for the arrhythmias. However response to these medications is poor. Mortality is 5.5% in aconite poisoning.

CLEISTANTHUS COLLINUS

More commonly known as 'oduvanthazhai' (Tamil = leaves of the 'oduvan' plant). It is a plant poison seen mainly in South India, especially in Tamil Nadu and Puducherry regions. All parts of the plant are poisonous though it is the leaves that are consumed. It is most fatal when a decoction is made from the leaves. It is used mainly for suicidal purposes and is more common in women. The active principles are the glycosides cleistanthin A, cleistanthin B, collinusin and diphyllin. Their mechanism of action is not known.

Clinical features include pain abdomen, occasionally nausea and vomiting, giddiness and visual disturbances, initially. Later they may develop fever, tachycardia followed by bradycardia, tachypnoea followed by bradypnoea, refractory hypotension and muscle weakness. Sensorium is clear till the end. A few may also develop nonoliguric renal failure.

Laboratory features include leucocytosis, hypokalaemia, mild metabolic acidosis, blood gases show acute respiratory distress syndrome (ARDS) like picture, hyponatraemia and azotaemia in some. Hypokalaemia too is a prominent feature.

Treatment includes gastric lavage and supportive therapy. Hypokalaemia requires potassium supplementation both by oral and intravenous route. Most fatal poisonings will require ventilatory and inotropic support. Death results from respiratory failure or refractory hypotension or both.

Mortality is 100% in those who have respiratory failure or hypotension. Overall mortality is 20% in *Cleistanthus collinus* poisoning.

STRYCHNOS NUX-VOMICA

Nux-vomica seeds are round disc like seeds, one side being convex while the other concave. They are about 2 cm in size, grey to light brown in colour. Poisoning results only when the seeds are crushed and not when swallowed as a whole. The active principles are the alkaloids strychnine and brucine, the latter being more abundant in the bark of the tree. They act at the spinal anterior horn cells where they inhibit the post-synaptic inhibitor glycine by competitive antagonism. The result is uncontrolled contraction of all muscle groups.

Clinical features of poisoning set in rapidly within minutes to an hour and include a bitter taste in the mouth, choking sensation in the throat, difficulty in swallowing saliva with drooling, restlessness, apprehension, convulsions, intermittent spasms causing opisthotonos (backward bending) or emprosthotonos (forward bending) or pleurosthotonos (lateral bending), spasm of the facial muscles can cause *Risus sardonicus* (grin/smile on face). Spasm of the masseters with lockjaw is a late feature. In between spasms, the muscles are relaxed. The spasms and convulsions can cause asphyxia and cyanosis with sudden death. The increased muscle activity can be initiated by slight noise or movement of the patient or even flash of light. Rhabdomyolysis and acute renal failure can ensue. The whole episode lasts for 4 to 6 hours with complete recovery, if patient survives.

Treatment of the patient in a quiet darkroom is preferable. The muscle activity is controlled with anticonvulsants and in extreme cases, muscle paralysis with relaxants and ventilation. Adequate intravenous fluids are to be administered to prevent renal failure. Recovery is usual.

ODOLLAM POISONING

Cerbera odollam (manghas) is a common form of poisoning seen almost only in Kerala. It is the green fruit of the plant which is poisonous. It looks like a mango, the South Indian term for which is manghas. It is used mainly for suicidal purpose, less commonly for homicide or accident ingestion. When used for suicide, the kernel is mashed with jaggery or sugar and when used for homicide, it is mashed with spicy food to coverup the bitter taste. The active principle is cerberin, a glycoside. It acts similar to yellow oleander toxins.

The majority of the victims are women. Following ingestion they develop nausea, severe vomiting and pain abdomen. The main toxicity is on the heart where like oleander it causes various arrhythmias and hypotension. Hyperkalaemia is more common than in oleander poisoning and demands redressal.

Treatment is the same as oleander poisoning.

INDIAN HEMP POISONING

This is also known as *Cannabis sativa* or *indica*. It is used in various forms, viz. *ganja*, *charas*, majun and *bhang* or *sidhi*. Ganja and charas are smoked, *bhang* is a liquid intoxicant and majun is a confection. The active principle is delta 9 tetrahydro-cannabinol. Serious poisoning is rare and is mostly accidental and rarely homicidal. It is used to stupefy mainly rail passengers to relieve them of their belongings. It acts on the cannabinoid receptors (CB1, CB2) in the central nervous system (cerebral cortex, basal ganglia, hippocampus and spinal cord).

Clinical features consist initially of excitement with talkativeness, laughter, euphoria, excessive hunger especially for sweets, motor restlessness, bloodshot eyes and tachycardia. Later giddiness, unsteadiness, generalised paraesthesias and weakness, visual hallucinations and delirium develops. Finally patient goes into deep slumber. Death is rare but may occur, especially in individuals with diseased heart. However, during the stage of excitement they can cause damage to property and injure other persons fatally. The whole episode lasts for a few hours.

Treatment is supportive.

26.7 Drug Overdose

Nusrat Shafiq

"All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy."

– Paracelsus, 1567.

DRUG OVERDOSE

Drug overdose may be defined as the ingestion or application of a drug or other substance in quantities greater than what is recommended or generally practiced. It may be intentional (suicide, homicide) or accidental (error) intake or administration (parenteral, oral, inhalational or contact on skin/mucous membranes) of a drug or medicine. In the present chapter some commonly used drugs with therapeutic potential will be discussed.

Although the concept of Paracelsus about dose determining toxicity holds true till date, pharmacogenomics studies have demonstrated an individual variability of response to a drug. For instance, we now know that some individuals may be more sensitive to a particular drug and may experience toxicity when 'normal' doses are used. For example, individuals with either of the CYP2C9*2 and CYP2C9*3 variants metabolise coumarins slowly and usual doses of warfarin may cause toxicity.

GENERAL PRINCIPLES OF DEALING WITH A CASE OF DRUG OVERDOSE

Most of the symptoms produced are due to exaggeration of pharmacological actions of the drug.

In overdosage the pharmacokinetics of the drug may be altered and, in general, the drug effects appear sooner, peak later and last longer in overdosage. However, some drugs or sustained release preparations are absorbed slowly, distributed slowly or require metabolic activation ('toxic time bombs').

General examination of patient should be done with a view of a pattern of recognition. The conglomeration of signs and symptoms is called toxidrome and can broadly be categorised as excitatory or depressed.

Plasma concentrations may only serve as a guide and the patient, not the drug concentrations, need to be treated. Moreover, the facility for drug level estimation is not available everywhere and reports take time.

Chemical antidotes are not always available. Supportive measures are key to recovery. Physiological antidotes are very useful.

Decontamination of the gut is important for preventing further absorption. Activated charcoal, gastric lavage using saline, whole bowel irrigation, ipecac are the available alternatives. They should be used judiciously on a case-to-case basis.

Enhanced elimination has a limited role but may be important in some poisonings. Alkalinisation of urine to a pH of 8.0 by administering bicarbonate with normal saline and potassium replacement is useful in salicylate poisoning; gut dialysis using repeat-dose activated charcoal 0.5 gm/kg PO or NG every 4 hours may be useful for some drugs like theophylline, carbamazepine and phenobarbital. Haemodialysis may be needed in some cases (salicylates, methanol, ethylene glycol, lithium).

Discussed briefly herein is the management of overdosage of some commonly used drugs:

Acetaminophen (Paracetamol)

The reactive metabolite of acetaminophen, N-acetyl-p-benzoquinoneimine (NAPQ) combines with cell structures causing hepato-cellular damage following acetaminophen overdose. Glutathione (conjugates NAPQ, removing it) stores are overwhelmed when this reactive metabolite is produced in excess.

Presentation

The signs and symptoms vary depending on the time after ingestion a patient presents (**Table 1**).

Table 1: Signs and Symptoms of Drug Overdose

Time since Ingestion	Signs and Symptoms
Phase I (0-24 h)	Anorexia, nausea, vomiting
Phase II (24-72 h)	Right upper quadrant pain, elevated liver enzymes, PT and INR may be elevated
Phase III (72-96 h)	Vomiting, symptoms of liver failure, renal failure and pancreatitis may occur
Phase IV (>4 days)	Resolution of symptoms or progression to fatality

Management

A normogram (**Figure 1**) based on plasma acetaminophen concentrations, drawn no less than 4 hours after ingestion, serves as a guide for management. *Importantly, in most of the Indian centres, facilities for the estimation of serum acetaminophen concentrations are not available.*

N-acetylcysteine is the treatment of choice. It is a sulfhydryl compound that serves as a substitute of glutathione. Both oral (140 mg/kg, followed 4 hours later by 70 mg/kg every four hours for 17 doses) and intravenous routes (150 mg/kg in 200 mL of D5W infused over 1 hour, followed by 50 mg/kg in 500 mL of D5 W over 4 hours and then 100 mg/kg in 1000 mL of D5W over 16 hours) may be used. Possibility of anaphylactoid reaction with N-acetylcysteine may necessitate the use of antihistamine and/or epinephrine.

Benzodiazepines (BDZ)

Benzodiazepines are generally, considered safe and their overdose alone is seldom fatal though they have a habit-forming potential. Exaggerated action at the inhibitory GABA receptor is the cause of central nervous system (CNS) depression.

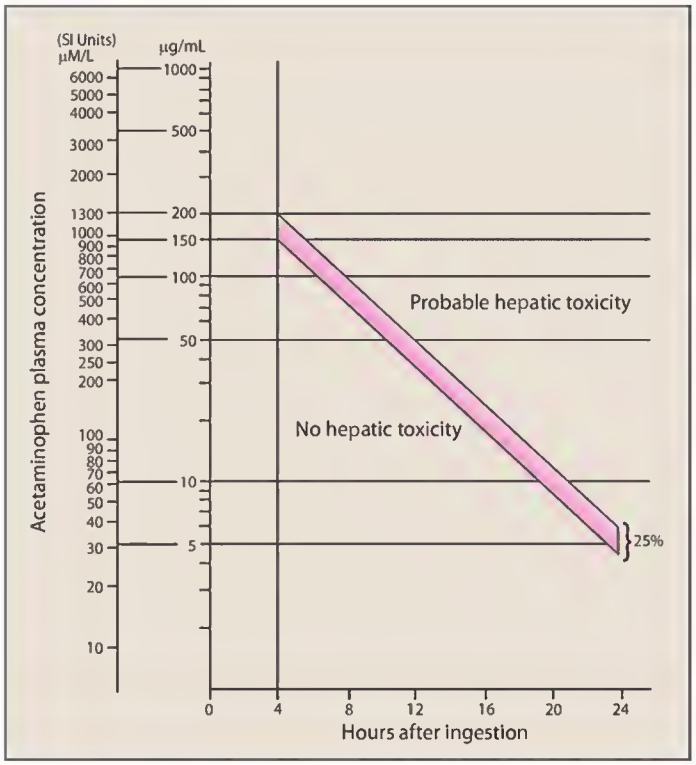

Figure 1: Semi-logarithmic plot of plasma acetaminophen levels vs time. *Source: Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. Pediatrics 1975; 55 (6): 871-6.*

Presentation

Reversible impairment of consciousness, nystagmus, reduced cognition, slurred speech occurs, very rarely deep coma and respiratory depression may occur. Respiratory depression is usually not profound. Anxiety, insomnia and sometimes convulsions may be precipitated on recovery from overdosage.

Management

Flumazenil is a competitive antagonist of benzodiazepine at GABA receptor and usually reverses the symptoms rapidly. It is given as 0.1 to 0.2 mg IV doses, repeated every 1 minute to a total dose of 1 mg at one time or 3 mg in 1 hour; or as 0.1 mg/min infusion. Inadequate response to a dose of 5 mg of flumazenil should make one suspect of an alternative diagnosis. Flumazenil itself may precipitate seizures especially if barbiturates or tricyclic antidepressants were also taken simultaneously.

Antidepressants

Antidepressants were the seventh leading cause of toxic exposures in 2008, according to the US National Poison Data System Annual report and led to 80 deaths. Out of the three groups of drugs are generally used as antidepressants – the tricyclic amines (TCAs), selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitors (MAOI), overdosage due to TCAs is common.

Presentation

In case of overdosage with TCA onset of symptoms typically occurs within 2 hours of ingestion and deterioration occurs rapidly. Lethargy, dry mouth, mydriasis, urinary retention, tachycardia and hypotension (may be refractory), prolongation of QT interval progressing to fatal ventricular arrhythmias are the key presenting features. Coma, delirium, seizures, and hyperthermia may also occur.

Rather than overdosage, drug-drug interaction in case of SSRIs may acutely raise the serotonin levels leading to a neuro-autonomic syndrome, serotonin syndrome. The presentation includes confusion, agitation, hyperthermias, diaphoresis, tachycardia, hypertension, myoclonus, rigidity, tremor, ataxia, and nystagmus. The condition usually resolves within 1 to 3 days.

Management

For overdosage with TCAs, activated charcoal may help since delayed gastric emptying caused by anticholinergic effect occurs commonly. Serum alkalinisation with intravenous sodium bicarbonate has been the mainstay of therapy in TCA-induced cardiovascular toxicity, particularly QRS prolongation (>160 ms). For ventricular tachycardia, overdrive pacing or lidocaine may be used. Hypotension should be treated with intravascular fluids, norepinephrine or dopamine. Benzodiazepines are used to suppress seizures. Animal studies have shown hypertonic saline to be effective in reversing TCA toxicity but human data are lacking. Physostigmine, should not be used in treating TCA toxicity because of the reported cases of physostigmine-induced seizures and asystole.

Salicylates

Salicylate overdose often occurs in children and can be fatal. The morbidity and mortality associated with an acute overdose are 1% and 16%, respectively, and with chronic intoxication is 30% and 25%, respectively. Fatal dose cannot be defined and death has been reported with 10 to 30 g of sodium salicylate ingestion. Plasma salicylate concentrations (**Table 2**) are often measurable at most centres. However, it should not be considered as indispensible for patient management.

Table 2: Categories for Assessing the Potential Severity and Morbidity of an Acute, Single Event, Nonenteric-coated, Salicylate Ingeston

Less than 150 mg/kg – No toxicity to mild toxicity
From 150 to 300 mg/kg – Mild-to-moderate toxicity
From 301 to 500 mg/kg – Serious toxicity
Greater than 500 mg/kg – Potentially lethal toxicity

Presentation

Salicylism refers to mild chronic intoxication characterised by headache, dizziness, tinnitus, difficulty in hearing, diminished vision, mental confusion, lassitude, drowsiness, sweating, hyperventilation, nausea, vomiting.

In acute overdosage, besides the above, CNS effects including confusion, convulsions and coma, hyperthermia and stimulation of respiratory system occurs. The latter is due to direct (stimulation of respiratory centre) and indirect (uncoupling of oxidative phosphorylation leading to accumulation of carbon dioxide) effects. Respiratory alkalosis with renal acidosis, dehydration with hypernatraemia ensues. Aerobic metabolism of glucose is impaired and hence hypoglycaemia may be dangerous. Petechiae due to impaired platelet function also may occur. Respiratory failure is the cause of death in these patients.

Management

Activated charcoal may be particularly helpful if enteric coated preparations have been ingested. Volume replenishment, restoration of acid-base and electrolyte balance, administration

of glucose and sodium bicarbonate (with the aim of maintaining a pH between 7.5 and 7.55 and achieving alkaline diuresis) is needed. Haemodialysis may be needed if all the above measures do not lead to improvement and/or plasma salicylate concentration is more than 1000 µg/mL.

Beta-Blockers

Over 9,000 cases of overdosage with beta-blockers have been reported with propranolol being the commonest agent implicated. A physiological depressant state is a common finding.

Presentation

Atrioventricular block (sotalol may cause tachyarrhythmias), hypoglycaemia and hyperkalaemia are the important features of beta-blocker poisoning. Although the half-life of these compounds is usually short (2 to 12 hour), their effects in overdose patients may be prolonged (>72 hour) because of decreased metabolism (a depressed cardiac output, reduced blood flow to the liver and kidneys), formation of active metabolites, saturation kinetics prolong elimination at the high plasma concentrations that typically occur with overdose, and more common use of long-acting preparations.

Management

Restoration of heart rate can be achieved by atropine, isoprenaline, amrinone, dopamine, dobutamine, epinephrine or norepinephrine. For managing hyperkalaemia and hypoglycaemia, glucose with insulin may be instituted. Because glucagon is both diagnostic and therapeutic, it can be administered empirically in a dose of 2 to 10 mg and response checked. It is considered drug of choice by many toxicologists and it acts by stimulating cAMP production through nonadrenergic pathways resulting in enhanced myocardial contractility, heart rate, and AV conduction. Benzodiazepines are the drugs of choice if seizures occur.

Calcium Channel Blockers (CCBs)

The three types of CCBs may all produce a physiologically depressed toxidrome. In 2008, the US National Poison Data System reported 10,398 exposures to CCBs, resulting in 12 deaths (0.11%) and 63 major outcomes (0.6%).

Presentation

Hypotension and bradycardia are typical presentations but reflex tachycardia after exposure to dihydropyridines can also occur. Pulmonary oedema, nausea, vomiting, hyperglycaemia are commonly present. Severe hypotension may lead to mesenteric ischaemia and colonic infarction. Paralytic ileus may be present. Since sustained release preparations are commonly used, presentations may be delayed. Even a single tablet of a CCB can be fatal in children.

Management

Restoration of cardiovascular parameters as for beta-blockers should be instituted. In severe cases a bolus dose of calcium chloride (10 to 20 mg/kg up to 1 to 3 g) is the preferred therapy. Bolus infusion of glucagon (0.05 to 0.20 mg/kg, over 1 to 2 minutes) is useful. For refractory cases, intravenous bolus of regular insulin with 50% dextrose may have some benefit.

PHENYTOIN

Symptoms of toxicity appear above plasma concentration of 20 µg/mL. However, there is a large inter-individual variation. Presentation of toxicity depends on the route of administration of phenytoin. Data from the United States of America suggest moderate morbidity rates of 22%, major morbidity in 1.88%, and fatality in 0.17% of phenytoin overdose cases.

Presentation

In an emergency setting when fosphenytoin intravenously is administered, toxicity symptoms (cardiac arrhythmias with hypotension and/or CNS depression) may appear if given at a fast rate (more than 150 mg of phenytoin sodium equivalents per minute).

Toxicity due to acute oral overdosage leads to cerebellar or vestibular symptoms. Chronic oral toxicity presentations include behavioural changes, increased frequency of seizures, gastrointestinal symptoms, gingival hyperplasia, and osteomalacia.

Management

GI decontamination to limit the systemic burden with multiple dose activated charcoal and control of seizures, if any, with benzodiazepines are the mainstay of treatment.

Digoxin

Various studies suggest that approximately 1.1% of outpatients on digoxin, and 2% to 18% of inpatients on digoxin have manifestations of toxicity. The incidence has declined due to increased awareness about drug interactions, decreased use of digoxin to treat heart failure and arrhythmias, and the availability of accurate rapid radioimmunoassays to monitor drug levels. Toxicity usually appears at a concentration > 2 ng/mL and is more likely to occur in those with impaired renal function, hypokalaemia, hypercalcaemia and hypomagnesaemia.

Presentation

Cardiac arrhythmias range from ventricular arrhythmias to atrioventricular blocks to sinus bradycardia. Non-cardiac symptoms include anorexia, nausea, vomiting, abdominal pain, halos, photophobia, fatigue, dizziness, delirium, and psychosis.

Management

Further doses of digoxin should be stopped. Conduction delays and blocks should be treated with atropine. Intravenous potassium may help in junctional or ventricular automaticity, lidocaine or phenytoin for ventricular tachyarrhythmias. Antidigoxin antibody is indicated for dysrhythmias associated with haemodynamic instability, altered mental status, K^+ >5 mEq/L, serum digoxin level >10 ng/mL in adults at steady state and ingestion of >10 mg in adults or >0.3 mg/kg in children. The dose is calculated as either (mg ingested) x 0.8/0.6 or [serum level (ng/mL) x 5.6 x body weight (kg)/1000]/0.6.

Methylxanthines

As is the case of digoxin, the number of reported cases of theophylline toxicity is decreasing for similar reasons. The toxicity may occur in two settings – in an emergency setting when aminophylline may be used, or chronic toxicity due to repeated oral administration.

Presentation

Rapid administration of aminophylline may even lead to sudden death. At concentrations more than 20 µg/mL, headache,

palpitation, nausea, hypotension, precordial pain, restlessness and agitation occur. Tachycardia, arrhythmias and seizures are important causes of concern.

With chronic toxicity, the concern is that of seizures which may be refractory to treatment.

Management

Decontamination with charcoal, especially if sustained release preparations are used, propranolol for the management of tachyarrhythmias with hypertension, any beta-blocker if hypertension is not present, diazepam, phenytoin or barbiturates for seizure control are the mainstay of treatment. Haemoperfusion or haemodialysis are indicated for unstable vital signs, seizures and plasma concentration of theophylline more than 80 to 100 µg/mL for acute overdose and 40 to 60 µg/mL for chronic exposure. Metoclopramide or ondansetron may be used for vomiting, and IV fluids/pressor agents for hypotension.

Iron

Iron overdose is one of the leading causes of fatality from toxicological agents due to non-intentional ingestion in children although the incidence has decreased considerably. Ingestion of 40 mg/kg or more of elemental iron is associated with serious toxicity. Generation of oxidative free radicals is the main mechanism of injury. Iron tablets can be visualised on abdominal radiograph if taken within 2 hours of ingestion.

Presentation

Iron poisoning may be classified into 5 distinct stages (**Table 3**). It is important to know them because the second recovery stage may lure the treating doctor into a false sense of security and lead to pre-mature discharge from the hospital.

Table 3: Stages of Iron Poisoning

Stage 1: Gastrointestinal
Usually occurs within 6 hours after exposure
Nausea and diarrhoea, often with excessive fluid and blood loss

Stage 2: Latent
This deceptive stage is characterised by resolution of GI symptoms
Usually occurs 6 to 12 hours after ingestion and may last for 24 hours

Stage 3: Metabolic/Cardiovascular
Metabolic acidosis and cardiovascular symptoms
Stupor and coma
Most patients die during this phase
It can start very early (6 to 8 hours), depending on severity of exposure, and it can last up to 2 days

Stage 4: Hepatic
Elevated liver enzymes and bilirubin levels with coagulopathy
Hypoglycaemia

Stage 5: Delayed
Scarring of the healing GI tract. The stomach and/or intestines may be affected, resulting in gastric outlet or intestinal obstruction
Experienced weeks after a severe poisoning

Management

Polyethylene glycol is the preferred agent for gut decontamination. Intravenous fluids and sodium bicarbonate may be needed for fluid and electrolyte balance. Patients with systemic symptoms should be given intravenous desferrioxamine. An initial dose of 1 g is given, either intravenously at a maximum rate of 15 mg/kg per hour, or by intramuscular injection; subsequent doses of 500 mg may be given, by infusion over 4 to 12 hours or intramuscularly at intervals of 4 to 12 hours, to a maximum of 6 g in 24 hours. Deferiprone is an orally active iron chelator used in the treatment of iron overload in patients with thalassaemia for whom desferrioxamine is unsuitable or ineffective. It may be given by mouthing doses of 25 mg/kg three times daily. Doses above 100 mg/kg daily are not recommended.

Warfarin

Warfarin overdose presents as excessive anti-coagulation reflected in elevated levels of Internationalised Normalised Ratio (INR) (**Table 4**).

Table 4: Excessive Anticoagulation Shown by Increased INR

INR Value	Management
0.5-6	Reduction in dose or withdrawn
6-8 (No bleeding/ Minor bleeding)	Stop warfarin
>8	Vitamin K1 (0.5 mg IV or 2.5 mg of IV dose given IV)
Major bleeding	Stop warfarin, Vitamin K (5 to 10 mg by slow intravenous infusion, concentrate of II, VII, IX, X) and fresh frozen plasma

Antipsychotics

Typical antipsychotics have by and large a wide therapeutic index.

Presentation

Overdosage may result in neuroleptic malignant syndrome characterised by extreme hyperthermia, 'lead pipe' skeletal muscle rigidity causing dyspnoea, dysphagia, and rhabdomyolysis, autonomic instability, fluctuating consciousness, leucocytosis, and elevated creatine phosphokinase.

The newer antipsychotic agents were evaluated for their effects in overdosage in a study in UK. Symptoms were most marked with clozapine, with a majority of patients experiencing agitation, dystonia, central nervous system (CNS) depression and tachycardia. Olanzapine and sulpiride produced a range of different symptoms, including cardiac arrhythmias with sulpiride and most patients who had taken risperidone were asymptomatic.

Management

The treatment of malignant syndrome includes immediate withdrawal of neuroleptic drugs, intravenous infusion of dantrolene, and oral administration of bromocriptine; or the combination of levodopa-carbidopa. Other measures include the use of benztropine, lorazepam if catatonic symptoms persist, or electroconvulsive therapy (ECT) if psychotic symptoms persist.

PROMETHAZINE

Promethazine, a first generation antihistaminic is commonly used for management of vomiting and cough.

Presentation

The important feature of promethazine overdose is delirium. Central nervous system (CNS) depression and anti-cholinergic

effects, including delirium, agitation and hallucinations are important features. Delirium may be masked by CNS depression. Dystonic reactions, psychosis in the absence of other anti-cholinergic symptoms or signs and neuroleptic malignant syndrome (NMS) may also occur.

Management

Dystonic reactions respond well to benztropine or diphenhydramine. Early administration of charcoal may reduce the occurrence of delirium.

Isoniazid

Acute ingestion of 1.5 g of INH can cause mild toxicity, 6 to 10 g causes severe toxicity and 15 g is usually fatal.

Presentation

Signs and symptoms of overdosage include slurred speech, hallucinations, metabolic acidosis, hyperglycaemia, respiratory distress or tachypnoea, convulsions and coma; fatalities may also occur.

Management

In adults an initial intravenous dose of pyridoxine hydrochloride equivalent to the estimated amount of isoniazid ingested (or, if the amount ingested is unknown, pyridoxine hydrochloride 5 g) has been recommended by the UK National Poisons Information Service for the management of convulsions; diazepam should also be given. For children the recommended dose of pyridoxine hydrochloride is 70 mg/kg (to a maximum of 5 g). If convulsions continue or recur, this dose may be repeated. Oral activated charcoal (50 g for adults and 10 to 15 g in children) may be considered if this is given within 1 hour of ingestion of isoniazid.

Lithium

Lithium is a narrow therapeutic index drug. Moreover it is subject to clinically significant drug interactions. Toxicity manifests more in those with renal failure, dehydration, hyponatraemia or those on diuretics.

Presentation

Acute intoxication is characterised by vomiting, diarrhoea, tremors, ataxia, coma, and convulsions. The more serious effects involve the nervous system and include mental confusion, hyper-reflexia, gross tremors, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma cardiac arrhythmias, hypotension, albuminuria, and death.

Management

There is no specific antidote for Li^+ intoxication, and treatment is supportive. Electrolyte and fluid balance is important. Dialysis is indicated for patients exhibiting symptoms of toxicity or patients with serum Li^+ concentrations greater than 4 mEq/L in acute overdoses or greater than 1.5 mEq/L in chronic overdoses.

Phenobarbitone

The plasma concentration of 10 to 35 microgram/mL is usually associated with attainment of therapeutic response.

Presentation

At high doses nystagmus and ataxia may occur and the typical barbiturate-induced respiratory depression may become severe. Overdosage can prove fatal; toxic effects include coma, severe respiratory and cardiovascular depression, with hypotension and shock leading to renal failure. Hypothermia may occur, with associated pyrexia during recovery. Skin blisters (bullae) occur in about 6% of patients with barbiturate overdose.

Management

Gastric lavage, multiple doses of activated charcoal (MDAC), airway protection, oxygenation, mechanical ventilation, IV fluids and vasopressors are the mainstay of treatment. The urinary elimination of phenobarbital (pKa of 7.2) may be enhanced with alkalinisation of the urine by sodium bicarbonate with the aim of maintaining urinary pH between 7.5 and 8. Haemodialysis or haemoperfusion are indicated for phenobarbital poisoning in the presence of renal failure and shock with ileus.

CONCLUSION

Drug overdosage is an important problem with significant morbidity and mortality. Though the ideal management would occur at poisoning and toxicology centres, more often than not these cases need to be managed at primary or secondary care centres. Supportive management is the mainstay of treatment and antidotes are helpful in very few poisonings. Limited dispensation policies, purchase on prescription could help bring down the incidence of suicidal overdosage.

26.8 Snake Bite Poisoning

HS Bawaskar

INTRODUCTION

Snake bite envenomation is a common acute life-threatening medical emergency. More than 200,000 snake bites are reported in the country and an estimated 35,000 to 50,000 people die each year. Majority of snake bite deaths go unreported as many victims go to traditional healers and many deaths occur before reaching hospital.

AETIOLOGY

There are about 216 species of snakes identifiable in India, of which 52 are poisonous. The major families of poisonous snakes in India are Elapidae which includes common cobra (*Naja naja*, **Figure 1A**), king cobra and common krait (*Bungarus caeruleus*, **Figure 1B**), Viperidae includes Russell's viper (**Figure 1C**), *Echis carinatus* (saw scaled or carpet viper, **Figure 1D**) and pit viper and hydrophiidae (sea snakes). Snake venom is not a substance evolved to attack man or big vertebrates, but is intended to paralyse the prey before swallowing. Venom secretion in all venomous snakes appears to vary in seasons. In warmer months its output is more than in the cold season. Similarly, darker the snake, more is the venom it secretes. Most snakes inject 10% of available venom in a single strike except Russell's viper which injects 75% of stored venom in one bite and is responsible for high morbidity and mortality in India.

Figure 1A: Common cobra (*Naja naja*).

Figure 1B: Common krait (*Bungarus caeruleus*).

Figure 1C: Russell's viper (*Vipera russellii*).

Figure 1D: Saw-scaled viper (*Echis carinatus*).

PATHOPHYSIOLOGY

Snake venoms are not single toxins but a cocktail of many components: enzymes, polynucleotide toxins, nontoxin proteins, carbohydrates, metals, lipids, free amino acids, nucleotides and biogenic amines. The content and potency of venom in any snake varies with size, age, diet, climate, and time of year. Moreover, a small snake's immature venom may not respond to routine anti-snake venom.

Procoagulant enzymes are the major factor in viper venom, which stimulates blood clotting and consumption of fibrinogen, causing disseminated intravascular coagulation (DIC). Russell's viper venom contains several different procoagulants which activate various steps of the clotting cascade. Fibrinolytic activity of the viper venom is so fast that sometimes within 30 minutes of the bite, the coagulation factors are so depleted that blood does not clot. Haemorrhagins are zinc metalloproteinases, which damage the endothelial lining of the blood vessels causing spurting of red blood cells and spontaneous systemic bleeding. Cytolytic or necrotic toxins damage the cell membranes and stimulate apoptosis. These digestive hydrolases, polypeptide toxins and other factors increase permeability resulting in local swelling and nonhealing ulcers and gangrene of the bitten part. Haemolytic and myolytic phospholipases A2 (PLA2) damage cell membranes, endothelium, skeletal muscle, nerve and red blood cells. Presynaptic neurotoxins are phospholipids A2 that damage nerve endings, initially releasing acetylcholine transmitter, then interfere with its release. Postsynaptic neurotoxins are

polypeptides which compete with acetylcholine for receptors in the neuromuscular junction and lead to curare-like paralysis (cobra venom).

The amount of venom injected at the time of bite depends on the species and size of the snake and the mechanical efficiency of the bites. At times snake may be able to control whether or not venom is to be injected at the time of bite. This is the reason why irrespective of bite by poisonous snake, sometimes there is no systemic sign of envenomation, i.e. dry bite.

ECHIS CARINATUS OR SAW-SCALED VIPER OR CARPET VIPER

It is 1 to 3 feet long, head is sub-ovate with short rounded snout, body is cylindrical, short and covered with rough, serrated flank scales, neck is distinctly constricted. It is pale brown or tawny with dark brown. A cruciform or trident or arrow type or just like the bird foot print shaped mark is seen on head. It flourishes in hot and humid climate in the coastal regions of India. It is alert, diurnal in habit and capable of quick movement when necessary. It hibernates in the winter. Readiness with which it bites on smallest provocation with extremely rapid strike makes it one of the more dangerous snakes. It forms a double coil in the form of figure of 8 with its head in the centre a striking position. It is viviparous producing 3 to 15 young at a time. It injects 0.0046 gram venom at the time of bite. Farmers, hunters, labourers, and persons walking barefoot in jungles and rocky areas are often bitten by this snake.

Clinical Manifestations

Local manifestations

Within an hour of the bite, swelling develops over the bitten part. Fang marks or abrasions with clotted blood are seen (**Figure 2**). Venom is of big molecular size and is circulated through the lymphatics, hence within 60 to 120 minutes the victim experiences a painful lymphadenopathy of the drainage area of the bitten part. Ecchymoses are seen over the bitten part or may spread over lymphatic drainage areas. Acute bleeding in the form of gum bleeds (**Figure 3**) or bleeding from abrasions on any other part of body or from vene-puncture sites is seen within 90 to 120 minutes of a bite. Occasionally, in untreated patients, bleeding can persist for 1 to 2 weeks in the form of blood-stained sputum, haematuria and then disappears of its own. Such patients are markedly anaemic and report to hospital for weakness or nonhealing bleeding cellulitis. Natural immunity against the *Echis carinatus* venom develops in cases of repeated bites by the same species in endemic areas as reported in Jammu region. Renal failure due to *Echis carinatus* has been reported from Puducherry and Jammu areas, but not from Maharashtra.

Figure 2: Two fang marks with bleeding spot at fang marks over the second toe due to *Echis* bite.

Figure 3: Acute bleeding from gums and oral cavity due to *Echis* bite.

RUSSELL'S VIPER OR *DABOIA* OR *VIPERA RUSSELLII SIAMENSIS*

It inhabits ten south Asian countries and ranks amongst one of the topmost important causes of snake bite mortality. While protecting the paddy and wheat from the rodent (rats) population, it kills many farmers unlucky enough to tread on it.

It is a 3 to 5 feet long snake; the head is covered with small scales and without shields. The body is massive and cylindrical, narrowing at both ends; the head is flat, triangular with short snout, large gold flecked eyes with vertical pupils and large open nostrils. Its belly is round with constricted neck. Typical rows of oval arranged in two rows is characteristic of Russell's viper. Its natural prey includes mice, rats, frogs, lizards, snakes, and birds. The young snakes are cannibalistic. The females produce 20 to 60 young usually around the month of June or July. Length of fangs in an adult snake is 16 mm and curved. The amount of venom injected at the time of bite is 63 ± 7 mg.

Clinical Manifestations

Local manifestations

The victim experiences severe local pain at the site of the bite, active bleeding from fangs marks within a few minutes, rapid swelling progressing to the whole limb within six to eight hours (**Figure 4**). Ecchymoses and blebs occur over the bitten part. Because of oedema of muscle and bleeding there is development of compartment syndrome characterised by swelling, painful passive movement, and loss of sensation over the nerve areas passing through the compartment. Subsequently, wet gangrene or nonhealing ulcers develop. Lymph nodes proximal to the bite become enlarged and tender.

Figure 4: Extensive swelling with ecchymosis due to Russell's viper bite and recovery after 8 days.

Systemic manifestations

Hypotension and shock are due to sudden liberation of bradykinin into the circulation, bleeding and loss of fluid in swollen part, bleeding in the adrenal glands, or peritoneal or massive blood loss by haematemesis or haemoptysis.

Haemostatic failure: Pro-coagulant content of venom initiates rapid thrombosis, hypofibrinogenaemia and consumptive coagulopathy. In human victims of Russell's viper bite, the injected dose of venom is insufficient to cause massive fatal intra-vascular coagulation within a minute of the bite, unlike in animals. Once the patient's blood has become defibrinated and incoagulable, spontaneous systemic bleeding ensues. Haematuria, bleeding in the skin, and pituitary haemorrhage can occur. Russell's snake bite victims can subsequently develop amenorrhoea, Sheehan's syndrome, loss of libido due to hypopituitarism, as reported from southern India. Enhanced capillary permeability is seen in the form of pleural and pericardial effusion, ascites, and conjunctival congestion/haemorrhage. High fatality is due to hypotension and resistant shock syndrome due to capillary leaks.

Renal failure: 20% to 40% cases subsequently develop anuria, oliguria and acute renal failure. Renal angle tenderness is the most important clinical sign for early diagnosis of renal failure. There is serial rise in blood urea and serum creatinine with acidosis and hyperkalaemia. Tubular damage by venom itself, interstitial nephritis, haemoglobinuria, hypotension, and microthrombi in the kidney contribute to acute tubular necrosis. Renal failure is the commonest cause of death.

Neurological effects: Ptosis, bulbar palsy, inter-nuclear ophthalmoplegia and respiratory paralysis due to presynaptic neuromuscular block in a Russell's viper bite has been reported from Kerala and Sri Lanka.

Green pit viper and bamboo pit snake bite cases, reported from Kerala, are characterised by local oedema and rarely a systemic bleeding disorder. Coagulopathy and renal failure has been reported due to Hump-nosed pit viper snake bite.

ELAPIDAE POISONING

Common Indian Krait (*Bungarus caeruleus*); local names: kala gandait, kala taro, kandar, manyar, chitti, kattu viriyan, valla pamboo.

Krait is the most poisonous snake, its venom being 10 times more poisonous than cobra venom. It is 1 to 4 feet long, with enlarged hexagonal vertebral scales, uniform white or red belly and narrow white crossbars on the back, more or less distinctly in pairs, the crossbars are typically absent near the head and neck region. The common krait resides in the vicinity of human habitation, near the wattle and daub, mud and small hut dwellings. Krait is a nocturnal, terrestrial snake that enters human dwellings in search of prey such as rats, mice, and lizards. It eats even the small snakes (cannibalism). The common krait is regarded as the most dangerous species of venomous snake in the Indian subcontinent. Most bites occur during the cooler months of June to December when snakes may, during the course of their hunting activity, linger in a person's bedding to take advantage of the warmth therein.

Clinical Manifestations

Majority of the cases of snake bite are reported between 11 pm to 5 am, usually when the person is asleep and the reflexes are greatly diminished; and the krait, having sharp small fangs, injects maximum venom in such a person. The victim might experience mild pain at the site of bite, paraesthesiae or numbness, without any local marks or swelling or bleed, hence the bite is neglected and falsely initially attributed to an ant or rat. Venom is small molecular size hence directly absorbed in the circulation. The venom stimulates the autonomic nervous system thus within 20 to 30 minutes of the bite, victims experience a transient abdominal colicky pain, bradycardia, sweating, vomiting, raised blood pressure. Subsequently, within 30 minutes to 18 hours the venom attacks presynaptic acetylcholine receptors resulting in ptosis (**Figures 5A to C**), pooling of saliva, dysphagia, dyspnoea, inter-nuclear opthalmoplegia, weakness of neck muscles, respiratory muscles and lastly the diaphragm. Patient complains of blurred vision,

Figures 5A to C: Manifestations of krait bite: (A) ptosis with bulbar palsy; (B) after recovery; and (C) fang marks over the ear lobules.

diplopia and lands in respiratory paralysis, coma and anoxic cardiac arrest. Venom induced paralysis of pupillary muscle causes non-reacting pupils. After recovery, a few patients had signs and symptoms of peripheral neuropathy. Many a times, patients succumb to iatrogenic respiratory infection or adult respiratory distress syndrome.

Cobra bite

Cobra bite tends to occur during the day time, when the transportation is more readily available. Moreover, because of its known severity, victims report to hospital early.

Cobra venom is a cardiotoxic, neurotoxic, haematotoxic and cytotoxic. The fangs of a cobra are small and sharp. Its venom is small molecular size hence rapidly absorbed into the circulation.

Soon after a bite, the victim experiences severe pain at the site of bite with fang marks covered with blood clots. Rapid development of swelling over the bitten part, ecchymoses, blebs, and massive damage of skin and subcutaneous tissue due to myocytolysis can occur. If the victim saw the biting hooded cobra, massive liberation of endogenous catecholamine into the circulation due to fear of death can actually result in lethal cardiac arrhythmias or cardiogenic shock due to massive myocardial infarction. Sinus bradycardia, A-V block and hypotension are due to cardio-depressant action of the venom. Sudden respiratory arrest without any other neurological manifestations can occur resulting in anoxic cardiac arrest. Rapid ptosis and bulbar palsy accompanied with respiratory depression can occur. Rarely, haematotoxic effects are seen. Blurring of vision and loss of accommodation are the earliest neurological signs of envenomation.

Locked-in syndrome

This may be seen in few cases, but such victims recover totally within 3 to 4 days if treated properly by maintaining oxygen saturation with proper ventilator support, maintaining electrolytes and nutrition and prevent iatrogenic infection. This phenomenon is due to blocked post-synaptic acetylcholine receptors including pupillary muscle which are rich in acetylcholine receptors.

Sea snakes

Sea snakes are seen all over the coastal region. Sea snake is accidentally handled by fishermen during fishing. Its venom is neurotoxic, myotoxic and haematotoxic. Soon after a bite, the victim experiences severe muscle pain, marked tenderness all over the muscles, trismus, muscular paralysis, respiratory arrest, without local manifestations at the site of bite. Myotoxic effects of venom causes hyperkalemia and myoglobinuria causing acute tubular necrosis.

Management

Figure 6 outlines the management of snake bite envenomation. Reassurance is important to allay anxiety and fear of death. Local incision, tight tourniquet or suction, and electric shock are to be discouraged. Patient should be shifted to the nearest equipped medical facility. Immobilisation of the bitten part by a splint, keeping the bitten part below heart level is preferred. It is worthy to apply crepe bandage (with a pressure enough that one can easily introduce the finger between skin and bandage) to krait bite case if victim took more than 30 minutes but less than 2 to 3 hours to reach the hospital. This helps to delay the absorption of venom and moreover, may prevent rapid development of respiratory paralysis.

Treatment with anti-snake venom (ASV)

History of snake bite or evidence of fang marks are not an indication for administration of ASV. There should be signs and symptoms suggestive of envenomation.

Initially, 100 mL ASV is to be added to 200 mL of crystalloid solution and administered over 60 minutes by intravenous route in a victim of krait, cobra and Russell's viper envenomation. It

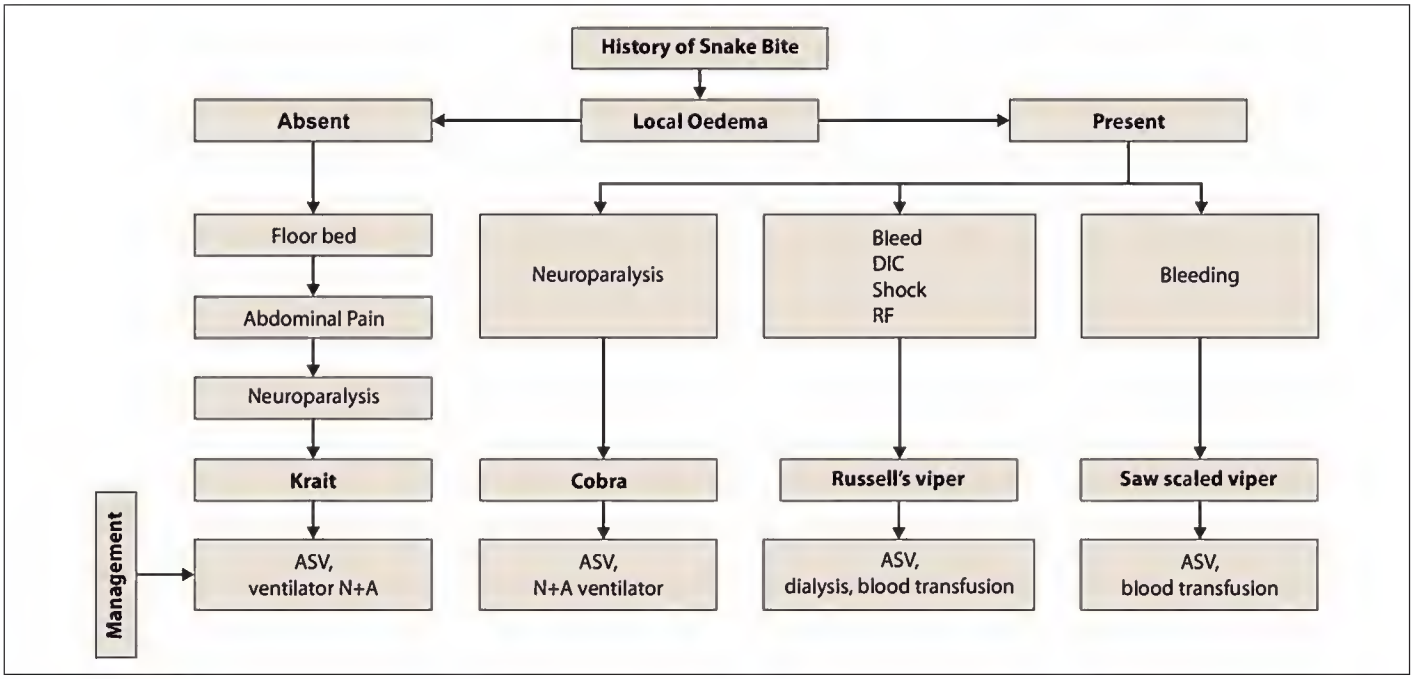

Figure 6: Flow chart for management of venomous snake bite.

ASV = Anti-snake venom; N = Neostigmine; A = Atropine; RF = Renal failure; DIC = Disseminated intravascular coagulation

neutralises the circulating venom. While the venom is absorbed slowly from the site of the bite, which acts as a depot, can be neutralised by 20 to 30 mL of ASV at 6-hourly intervals.

In case of elapidae envenomation, 50 mL of ASV can be administered if there is no improvement within 30 to 60 minutes after the initial dose; while the total initial dose required for *Echis carinatus* envenomation is 20 to 40 mL over one hour and 20 mL over the next 24 hours.

ASV may be administered even after 12 to 14 days after viper bite if systemic toxicity is present. After the initial dose of ASV, if active bleeding such as haematemesis, haematuria, bleeds from the wound do not disappear within 20 to 30 minutes, particularly in viper bite, one can repeat 20 to 50 mL ASV as an extra bolus.

Twenty minute whole blood clotting test (20WBCT) is the gold standard bedside test and can be performed by unskilled staff. Before injecting ASV, from same venepuncture 2 to 3 mL of blood is withdrawn and added to a dry glass tube (not washed with detergent), and then kept standing for 20 minutes. If the tip of the blood did not clot, hypofibrinogenaemia is confirmed. This test should not be repeated earlier than 6 hours after administration of ASV, as the liver takes six hours for synthesis of coagulant factors. 20WBCT test decides further requirement of ASV. This test is important for diagnosis and also indicates the improvement.

Once the venom gets attached to the target organs (receptors) such as neuromuscular receptors, red blood cells, platelets, renal tubules, and myocardium, then any amount of ASV will not be able to reverse the effects.

Elapidae venom blocks the acetylcholine receptors, this action of venom can be reversed by neostigmine in the dose of 25 microgram per kg per hour preceded by atropine. Post-synaptic receptors blocked by cobra venom can be totally reversed by choline-esterase inhibitor, while in krait bite venom which blocks both pre- and post-synaptic receptors, neostigmine may help to delay the respiratory depression in early stage. Need for artificial ventilation is indicated by grade 3 power, pulling of saliva, or tidal volume below 200 mL.

Hypotension, bradycardia are to be treated with dopamine drip and atropine. Complete heart block in cobra bite needs isoprenaline drip, ASV and temporary pacemaker.

Renal failure: Early administration of ASV, mannitol, diuretic and acetylcysteine may help to prevent the renal failure in Russell's viper bite. Close monitoring of urine output is important to detect early renal failure in Russell's viper bite. Early renal failure is treated by intravenous frusemide 200 to 500 mg or torsemide by continuous intravenous drip and dopamine drip with fluid restriction. Haemodialysis or peritoneal dialysis may also need to be offered in established renal failure cases.

Profuse bleeding can be treated by blood transfusion. Shock due to accumulation of fluid in compartment syndrome or muscle damage can be prevented by surgical decompression, but the following criteria should be fulfilled before any surgical procedure: (1) marked tenderness over muscles, (2) pain during passive movement of muscles, and (3) loss of sensation or hypo-aesthesia in the supply of a nerve passing through the compartment.

Hyperkalaemia is managed on standard lines – intravenous calcium gluconate, diuretics, insulin-glucose drip, salbutamol nebulisation and if required, dialysis.

Anaphylaxis can result from ASV, but test dose of ASV is not essential. Recently, it is reported that adrenaline can be used as prophylaxis before starting ASV. Earliest symptom of anaphylaxis is vomiting sensation, warm sensation in ears or head, itching behind ears, urticaria, itching all over body, hypotension, tachycardia, bronchospasm, dysphagia, swelling of tongue and lip, feeling of obstruction in throat. ASV should not be given by rapid intravenous bolus as it may activate complement and result in a severe reaction. One should keep watch for appearance of anaphylaxis for 10 to 180 minutes after administration of ASV. While diluting ASV if there is a precipitate, it should be discarded as such precipitated proteins are more likely to cause severe anaphylaxis.

Intra-muscular injection should be avoided if the patient's blood fails to clot.

Total requirement of ASV dose can be reduced by preparing mono-specific ASV or purified F(ab)2 ASV.

ELISA kit for detection of venom antigen helps a treating doctor know the exact species of snake and even help to monitor the circulating venom antigen, thus the dose of ASV.

Prevention

Firewood, dry cow dung, cattle shed and rubble should be kept away from residential areas. Old storage rubble, particularly in old house, should be handled in full sunlight. Rubble in the attic should not be handled blindly. Barefoot walking in darkness for open toilet in grown grass should be avoided, or one should go out with a torch and a heavy stick so as to vibrate the place before stepping. Proper care of rats, mice and lizards must be taken. No attempt should be made to catch the snake or to kill it. Killed snake should not be handled. Thick electric rubber gloves with rubber shoes should be worn at the time of handling the crops husk. A bamboo cot with scrupulous use of a mosquito net prevents scorpion sting, krait and mosquito bite alike. The victim should report as early as possible to the nearby primary health centre where enough storage of ASV is kept ready.

Training in appropriate use of antivenom and protocol of indications for its use should be arranged at general hospital level to ease the crisis of supply of ASV. It is important to note that already applied tourniquet to the part at site of venomous snake bite should not be released until full dose of snake antivenom is administered.

26.9 Scorpion Sting

HS Bawaskar

Scorpion envenomation is a major public health problem in tropical and sub-tropical countries, especially in Africa, Middle-East, Latin America and India. At times it poses a significant life-threatening acute time limiting cardiovascular emergency. Irrespective of different species of scorpion, similar cardiovascular effects are reported. Irrespective of the understanding of the pathophysiology and management, the morbidity and fatality remains high in rural areas due to nonexistent medical facilities and the delay in hospitalisation due to superstitions and faith in village healers. Scorpion envenoming has been underestimated as this problem is faced by majority of underdeveloped and developing countries. Since the advent of prazosin therapy the fatality has dropped from 29% to less than 1%.

The Indian red scorpion *Mesobuthus tamulus* (**Figure 1**) is the most lethal amongst all the poisonous species of scorpions.

Figure 1: Photograph showing an Indian red scorpion (*Mesobuthus tamulus*).

The scorpion envenomation has been frequently reported from Puducherry, Karnataka, Tamil Nadu, Andhra Pradesh, Saurashtra, Uttar Pradesh, Bihar and Marathwada and Western Maharashtra. Thousands of scorpion stings are reported annually from India and 15% to 20% of these stings manifest with systemic symptoms. Farmers are more prone to get stung by scorpion during handling debris and paddy husk in the months of April to early June and September to October as due to sudden rise in environmental temperature, scorpions come out of their hides. The sting during these months is more potent and prone to serious envenomation. Scorpion is nocturnal in habit and people walking bare foot become their victim more commonly.

SCORPION

Nearly 1,000 species of scorpion are known worldwide, which belongs to six families. However, only the scorpion belonging to the family *Buthidae*, secretes neurotoxic venom that is toxic to human; around 86 species of this family are found in India. *M. tamulus*, an Indian red scorpion, is venomous and its envenomation is fatal if not treated in time. Its claws are red coloured, but tail, legs and body is covered with *khaki* coloured cuticles. It is 2.5 to 4 inches in length. The tail consists of stout segments with terminal bulb containing pair of telson venom secreting salivary glands. It actively secretes venom at the time of sting by a sharp semi-curved stinger. The stinger is 2 to 4 mm in size and human skin thickness is 1.5 to 4 mm. Scorpion venom is rich in neurotoxin.

The black scorpion *Palmaneus gravimanus* is less poisonous (**Figure 2**). It is seen in Kerala, Vidharbha and Marathwada region of India. It is bigger in size as compared to red scorpion. It inflicts severe and excruciating painful sting. Its claws are broad and thick and strong while tail consists of thin segments.

Figure 2: Photograph showing a black scorpion (*Palmaneus gravimanus*).

Scorpion Venom

All scorpion species secrete venom. Venom is a mixture of various active substances; of these neurotoxins are the most important. Neurotoxins consist of different small sized proteins with sodium and potassium cations, which interfere with the neurotransmission. Venom action on neurotransmitter is rapid and fast. It contains peptide neurotoxin that opens the sodium channels (beta-toxin). The scorpion venom depolarises the cell membrane; in addition it also inhibits the deactivation of sodium channels (alpha-toxin). There is massive release of endogenous catecholamines in to the circulation due to delayed activation of sodium neuronal channel by the venom. The venom of the *M. tamulus* (Indian red scorpion), *Buthus martensii* (Chinese scorpion) and *Leiurus quinquestriatus* (yellow scorpion) causes autonomic storm by stimulating autonomic nervous system (ANS). Charybdotoxin another component of the venom inhibits the calcium dependent potassium channels; similarly iberiotoxin isolated from *M. tamulus* has similar action on potassium channels. Scorpion venom also contains serotonin, which may cause local pain at the site of the sting. The venom of Tityus species has a kallikrein inhibitor causing raised bradykinin levels. Venom of *Tityus serrulatus* from Trinidad is pancreotoxic, responsible for the development of acute pancreatitis.

CLINICAL MANIFESTATIONS

Clinical effects of the envenoming depend upon the species of scorpion and dose of venom injected at the time of sting. The severity of envenoming is related to age, size of scorpion and the season of the sting. High fatality rate is seen in children. The early or pre-monitory clinical manifestations characterised by vomiting, profuse sweating all over the body (**Figure 3**), priapism (**Figure 4**), cold extremities and mild tolerable pain. This pain becomes severe and excruciating when extremities become warm, a sign of recovery.

Clinical presentations can be divided into following two grades:

1. Local manifestations—severe local pain without systemic involvement
2. Systemic manifestations.

Figure 4: Priapism.

Local Manifestations

Local pain or severe excruciating pain is the only clinical manifestation seen in 35% of cases in a recent series. In 57%, 33% and 11% cases; lower extremities, upper extremities and the other part of the body are the sites of sting, respectively. Severe pain radiates along the corresponding dermatomes. Local oedema, urticaria, fasciculation and spasm of underlying muscles are seen at the site of sting due to persistent stimulation of pain conducting receptors and the liberated serotonin. Due to pain there is transient bradycardia, transient rise in blood pressure and mild sweating with warm extremities. Sudden tap at the site of sting induces severe pain and sudden withdrawal of the part called 'tap sign'. Patient continuously moves the stung part of body or holds it firmly to find a comfortable position.

Systemic Manifestations

Soon after scorpion sting the victim suffers from the autonomic storm and shows all pre-monitory signs and symptoms. The red scorpion venom is potent sodium channel activator and stimulates the ANS resulting in sudden pouring of catecholamines in the circulation. Both sympathetic and parasympathetic twigs are stimulated leading to 'autonomic storm', characterised by initial parasympathetic stimulation clinically detected in form of vomiting once or twice, profuse sweating all over the body (4 to 12 hours), ropy salivation (**Figure 5**), priapism (6 to 8 hours), mydriasis, bradycardia, hypotension, transient premature

Figure 3: Profuse sweating.

Figure 5: Ropy salivation.

ventricular beats. Sympathetic stimulation is characterised by propped eyes, puffy and anxious facies, oculogyric crisis, chest discomfort, perioral paraesthesias, at times tingling and numbness all over body and cool extremities. Skin over hands, feet, palm and sole look like a washer-man hands as they appears finely wrinkled and cold. Clinical manifestations at times are apparently diverse irrespective of similar pathology. In some patients there is minimal local pain on arrival but as the peripheral circulation improves with time and warming, they start experiencing excruciating pain. Severe transient muscle spasm may occur due to the loss of electrolytes.

Clinical manifestations depends upon the time elapsed between sting and hospitalisation and the treatment received at periphery. The major manifestation includes hypertensive crisis and pulmonary oedema (PE) which may be fatal if not treated timely.

Hypertension

Upto 45% of victims with systemic involvement were found to have hypertension when reported within 15 minutes to 11 hours after the sting. Children may present with agitated look, confusion, generalised convulsion, transient hemiplegia, oculogyric crisis, bilateral extensor plantar response, propped up eyes and a puffy face suggestive of hypertensive crisis. It may be difficult to measure accurate blood pressure in such children. Majority of these cases complained of headache, chest discomfort, suffocation, giddiness and paraesthesia.

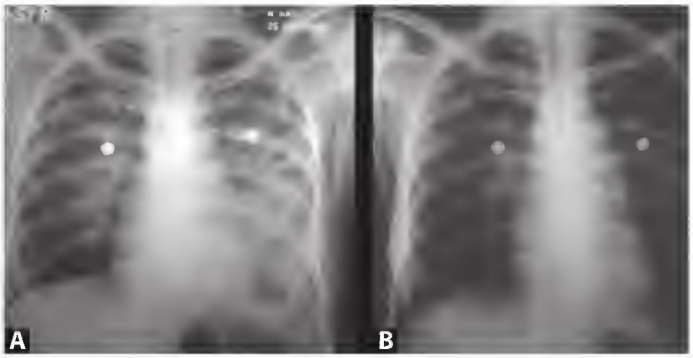
Transient initial hypotension is due to hypovolaemia secondary to acetylcholine excess, it is further aggravated by hot climatic conditions in summer months of the tropics.

Pulmonary oedema

PE occurs in upto 30% severe scorpion sting cases with respiratory failure. PE develops within 30 minutes to maximum 36 hours. In up to 8% cases massive PE may be life-threatening. Clinically PE can be suspected when respiratory rate is >24 per minute, orthopnoea, intractable cough, low volume fast thready pulse, narrow pulse pressure, summation gallops, systolic murmur and moist basal rales, central cyanosis. Intractable cough with massive expectoration of blood mixed froth from the mouth and nostril with central cyanosis, hypo- or hyper-tension and loud death rattle sound heard are suggestive of massive PE.

Alpha receptors stimulation plays an important role in the pathogenesis of PE. Disseminated intravascular coagulation, coma, convulsion, miosis, mydriasis and hemiplegia, aphasia, cerebral infarction, transient bilateral cerebellar syndrome and subdural hematoma have been reported during pre-prazosin era. Acute renal failure due to scorpion sting is rare. However, ill-treated, delayed reporting of a case may result in death due to multi-system organ failure and acute respiratory distress syndrome.

After 20 to 30 hours of recovery from autonomic storm, the victim develops asymptomatic warm extremities, accompanied with bradycardia, hypotension with prolonged QTc interval (0.50 to 0.65 sec) on electrocardiogram (ECG). He may look exhausted. The depletion of tissue catecholamines following autonomic storm is the cause and patient usually recovers within 72 to 96 hours without any intervention. This phenomenon does not occur if victim receives scorpion antivenom and prazosin simultaneously.



Fatality

Victim can die suddenly due to ventricular arrhythmias which usually occur within 15 to 30 minutes of sting. Many victims die from severe PE, brain haemorrhage and multi-system organ failure, if not treated properly and in time.

INVESTIGATIONS

Total leucocyte counts are raised to 11,000 to 26,000 due to venom induced interleukin-6 and tumour necrosis factor-α release. Cardiac CPK MB is raised. Reduction in serum amylase and serum calcium levels may be observed. There is raised serum glucose, potassium and reduction in insulin level.

Chest radiograph may reveal unilateral or bilateral batwing or patchy PE (**Figures 6A and B**). At times secondary respiratory infection in the form of consolidation is seen in a hospitalised patient recovering from PE. Mild cardiomegaly may be present. In author's series of cases of PE due to scorpion sting, the follow-up of more than 15 years did not show any cardiovascular abnormality.

Figures 6A and B: Chest radiographs showings (A) pulmonary oedema in a patient and (B) after recovery.

Electrocardiogram

ECG is one of the most important diagnostic and easily available investigation. Not a single victim with systemic involvement has normal ECG. Sinus bradycardia seen in early hypertensive cases with a heart rate of 42 to 60 per minute, ussually persisted for 3 to 4 hours. The other common findings are ventricular premature contraction, couplets, transient nonsustained ventricular tachycardia and rarely fatal ventricular arrhythmias (**Figure 7**). The sinus tachycardia, injury to conducting system in the form of left anterior hemiblock, bundle branch block, complete heart block and marked tented T waves may be the other common findings. The tall T waves may mimic acute myocardial infarction (AMI). Elevated ST segment with small Q wave is also often seen in lead 1 and AVL. Severe PE cases showed low voltage pattern with PQRST alterans with ST segment depression. Recovering victim's ECG showed large T wave with wide base and round top suggestive of delayed depolarisation with prolonged QTc, accompanied with asymptomatic bradycardia and hypotension. The severity of ECG changes did not correlate with clinical condition.

Echocardiography

Echocardiography shows poor global contractility 12 to 15 hours after sting with low ejection fraction, decreased systolic ventricular performance and mitral incompetence. Abnormal diastolic filling persisted for five days to four weeks. There is

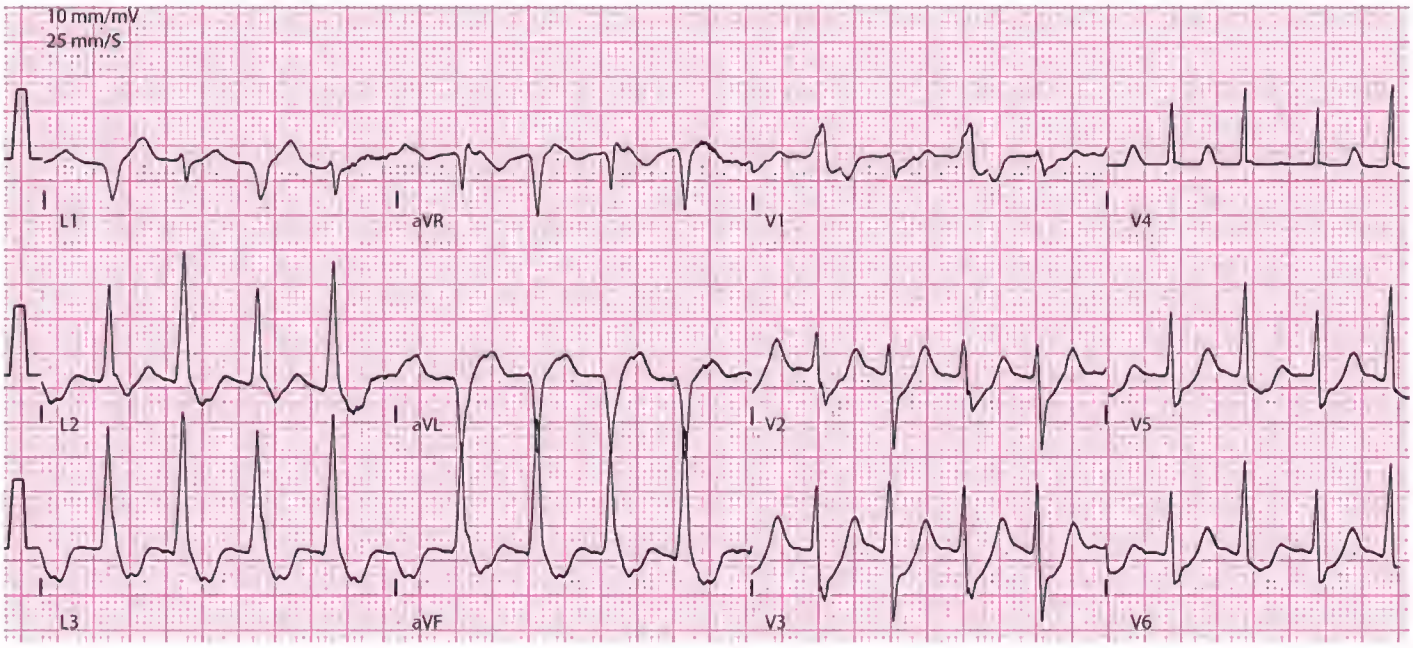


Figure 7: Electrocardiogram of a patient showing ventricular ectopics.

good echocardiographic correlation between clinical improvement and return of left ventricular function.

Mild envenomation causes severe vasoconstriction and hypertension; while predominant left ventricular dysfunction with normal systemic vascular resistance with PE is seen in severe scorpion sting. However, severe hypotension depends upon the fluid balance, while hypotension and shock with warm extremities occurs in terminal stage due to biventricular dysfunction and terminal vasodilation (warm shock).

MANAGEMENT

No scorpion sting should be taken as benign unless observed for 24 hours, irrespective of species involved. On the basis of pathophysiology, therapeutic effort should be directed against venom, the clinical manifestations of the over stimulated ANS and after effects of excessive catecholamine and correction of hypovolaemia. The incision at the sting site or tourniquet is not advisable and patients who come for medical care after 4 hours of sting and do not show signs of systemic envenomation can be treated symptomatically without prazosin or scorpion antivenom.

Local Envenomation

Mild pain can be abolished by application of ice packs over the site of sting. Severe excruciating pain can be transiently relieved by local anaesthesia (lignocaine without adrenaline). However, oral diazepam and nonsteroidal anti-inflammatory drugs (NSAIDs) with first initial dose of lignocaine can give prolonged relief from pain. At times, severe intolerable pain patient tossing in bed without signs of autonomic storm injectable opoid (pentazocin).

Systemic Envenomation

Dehydration leading to hypovolaemia is due to vomiting, excessive salivation and profuse sweating. It should be corrected by oral rehydration. Intravenous crystalloids or hydration by nasogastric tube may be necessary in a confused and agitated victim. Fluid deficit must be corrected since hypovolaemia is one of the proposed mechanisms of shock syndrome in scorpion sting. Electrolyte imbalance should also be corrected.

Prazosin

An α-1 adrenergic receptor blocker reduces preload, left ventricular impedance without causing tachycardia. It reverses the metabolic syndrome evoked due to excessive catecholamines release. Prazosin is a pharmacological and physiological antidote to scorpion venom actions. It also inhibits sympathetic outflow in CNS. It inhibits phosphodiesterase, thereby enhancing a cGMP level which is one of the mediators of nitric oxide synthesis. It enhances insulin secretion which is inhibited by venom. Thus, its pharmacological properties can antagonise the haemodynamic, hormonal and metabolic effects of scorpion venom (**Figure 8**). It can be administered orally in a dose of 250 to 500 µg/Kg in children and 500 to 1000 µg/kg

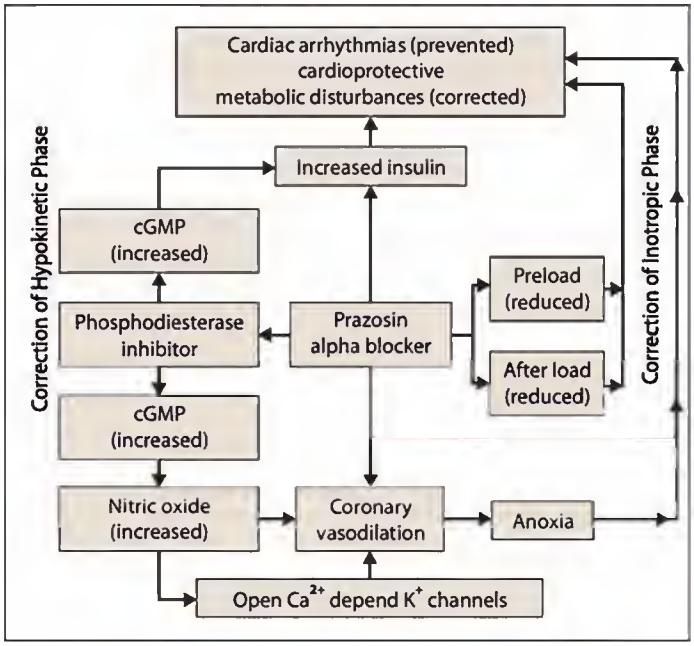

Figure 8: Flow chart showing effects of prazosin (venom antidote).

in adults and should be repeated every 3 hourly until the signs of clinical improvement appear or till dry and cool extremities persist. If the initial dose has been vomited, it should be repeated. Due care should be taken to avoid postural fall in blood pressure which is a known side-effect of prazosin (first dose phenomenon). Postural hypotension should be treated by lowered head position and intravenous fluids. Since the advent of prazosin the fatality due to severe scorpion sting has reduced to less than 1%. Prazosin is poor man's scorpion antivenom.

Scorpion antivenom

It is available for clinical use. Venom causes transient parasympathetic and prolonged sympathetic stimulation. Ongoing cholinergic phenomenon is suggestive of free circulating scorpion venom, which can be neutralised by antivenom, while sympathetic stimulation suggests after effects and fatality is due to sympathetic over activity. Scorpion antivenom is more effective if a victim is brought in a stage of acetylcholine excess that is early stages of scorpion sting. Early use of scorpion antivenom in addition to prazosin hastens the recovery. Total dose of antivenom required is 30 to 100 ml. However, scorpion antivenom is expensive and always in short supply. No test dose is required as there are high circulating catecholamines and anaphylaxis is very rare.

Supportive Management

PE is the most important cause of mortality and should be treated with propped up position, nasal oxygen, intravenous loop diuretics, oral prazosin. Massive PE may also require immediate oral nitroglycerin (NTG) spray to reduce the pulmonary congestion and intravenous NTG drip or if available sodium nitroprusside 4 to 5 µg/kg/minute. Blood pressure should be closely monitored and maintained at the level of systolic 80 to 90 mm Hg. Inotropic support with dopamine and dobutamine 5 to 15 mg/kg/minute is advocated for 36 to 48 hours in warm hypotensive shock patients. Unconscious patients with cardio-respiratory failure may also require invasive or non-invasive mechanical ventilatory support. A step-wise management of scorpion sting is shown in **Figure 9**.

Cardiac arrhythmias are many times self-limiting. Intravenous amiodarone should be used with caution as it may precipitate massive PE, marked bradycardia and cardiac arrest. Captopril, glucose insulin potassium drip and L-carnitine have also been tried to alleviate the venom effects on the heart but does not approved indication.

Atropine, steroids, antihistamines, beta-blockers, calcium channel blockers, excessive diuretics, adrenalines and narcotics are to be avoided as these do more harm than good in scorpion envenoming.

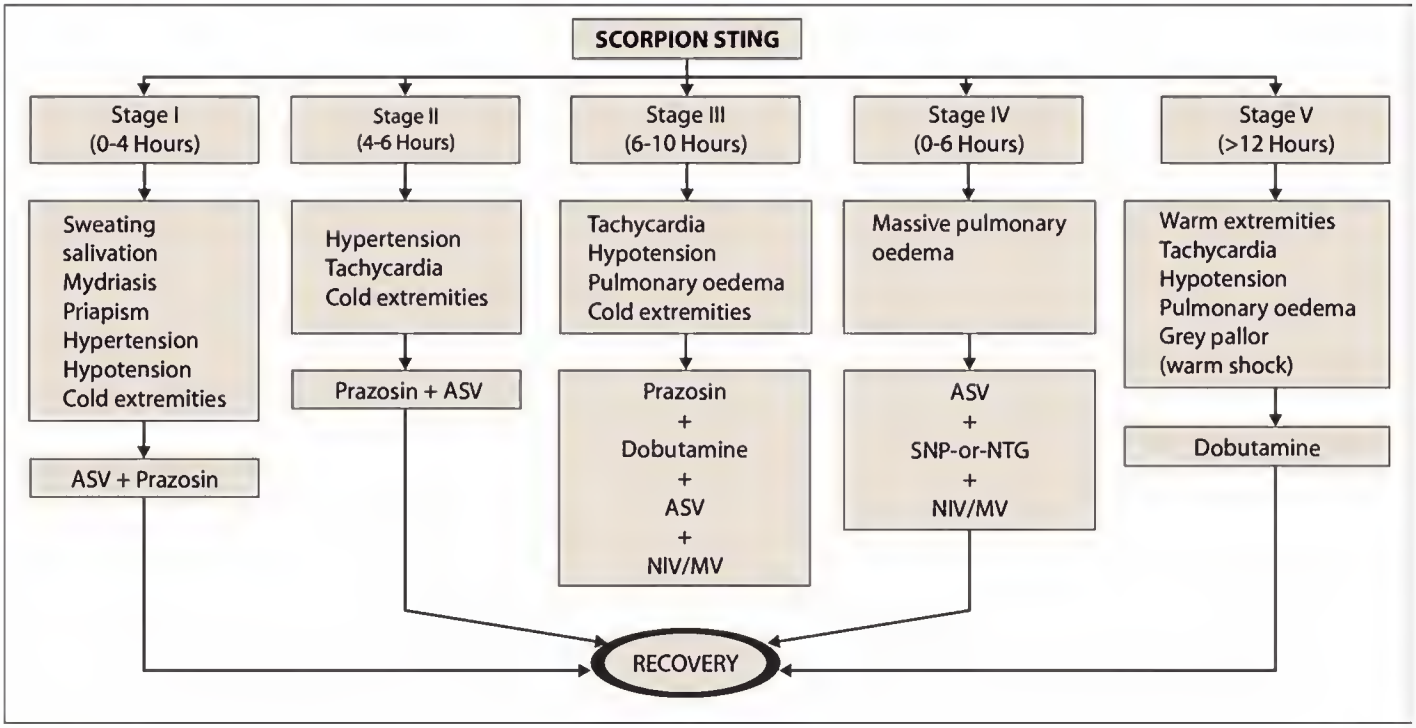

Figure 9: Management of scorpion sting.

ASV = Anti-scorpion venom; SNP = Sodium nitroprusside; NTG = Nitroglycerin; NIV = Non-invasive ventilation; MV = Mechanical ventilation

PREVENTION

Scorpions are killed by organophosphorous pesticides. A false ceiling of plastic sheet should be put under the roof of hut to prevent scorpions falling in bed from loose tiles of roof. Shoes and clothes should be checked before wearing. Shoes should be packed with paper or cloth so as to prevent the entry of scorpion in night. Hand gloves made of thick rubber should be worn while harvesting fire wood, dry cow dung, lifting paddy, *jowar* (sorghum) and sugar cane husk. Children should not be allowed to go outside in early darkness without shoes. Simple sandal or slipper did not prevent the sting. One should not put hand blindly in crevices, doors or old storage material during night hours and bedding or cot should kept at distance from mud house wall and one should not backrest on mud wall.

26.10 Fluorosis

D Raja Reddy

INTRODUCTION

Fluorine being electronegative and reactive of all elements does not occur in free form in the nature. This element combines directly with most elements and indirectly with few to form fluorides, which are the 13th commonest element in earth's crust. Fluorides being ubiquitous in nature are present in nearly all foods and natural waters. The relationship between optimum fluoride intake and decreased incidence of dental caries and osteoporosis has been recognised. Endemic skeletal fluorosis is a disease caused by excessive ingestion of fluorides through water, food or both. The upper limit of optimum fluoride level in drinking water for a tropical country like India is 0.5 ppm. The upper limit of safe total intake of fluoride from food and water per day for an adult is 6 mg. Biological effects of fluoride intoxication are related to the total amount of fluoride ingested whatever the source be it food, water, beverages or all.

INCIDENCE

First ever cases of endemic skeletal fluorosis in the world and its neurological manifestations were recorded from Podili, Darsi and Kanigiri areas of Prakasam district in Andhra Pradesh in 1937. Subsequently, the cases of fluorosis were reported from other regions of Andhra Pradesh and also from other parts of India and the world. It is now estimated that 66 million people are living in endemic areas of fluorosis, which are spread over 275 districts out of 619 in the country and these are located in 20 states and union territories, such as Andhra Pradesh, Assam, Bihar, Chhattisgarh, Delhi, Gujarat, Haryana, Jharkhand, Karnataka, Kerala, Jammu and Kashmir, Madhya Pradesh, Maharashtra, Orissa, Punjab, Rajasthan, Uttar Pradesh, Uttarakhand, Tamil Nadu and West Bengal. The populations in endemic areas are at risk of developing skeletal fluorosis and 6 million people are crippled because of it. Hence, skeletal fluorosis is a major public health problem not only in India but also in 25 odd countries.

EPIDEMIOLOGICAL STUDIES

Ten million of people living around the world are affected by fluorosis, and hence, factors governing the development of chronic fluoride intoxication need to be understood so that effective measures can be instituted to contain it. The factors which govern the causation of fluorosis are the following:

1. High levels of fluoride in drinking water supplies and foodstuffs in the endemic areas. Fluoride levels in natural waters in India vary from 0.2 ppm to 42.5 ppm. Fluorosis is predominantly a rural problem because 90% of rural water sources are ground water whereas all major cities get their water from perennial rivers, which have optimum levels of fluoride. Fifty per cent of ground water sources in our country have excess fluoride and the crops cultivated by water having high amounts of fluoride leads to high content of fluoride in cereals and vegetables in these areas. Hence, significant amounts of fluorides also come from food in endemic regions. The total daily intake of fluorides from water and food in three villages of high endemic areas of Nalgonda varied from 54.66 mg to 75.76 mg.
2. Tropical weather and hard manual labour activity increases the intake of water and fluoride.
3. Diets deficient in calcium, magnesium and vitamin C aggravate fluoride toxicity. Optimum intake of calcium in the diet reduces the amount of fluoride absorbed from the gut. Magnesium has a peculiar relationship with fluoride and its optimum intake helps in elimination of fluoride from the body. Vitamin C is beneficial in some way in reducing fluoride toxicity. Diets deficient in calories and calcium intake increases the incidence of skeletal fluorosis in endemic areas. The National Nutrition Monitoring Bureau and National Family Health survey reports from India reveal gross malnutrition of rural population and also their lower intake of calcium especially among growing children, which may explain the high incidence of fluorosis in rural areas of our country.
4. Renal disease aggravates the incidence of fluorosis by the increased deposition of fluoride in the bones since diseased kidneys cannot handle fluoride excretion from the body. This may explain the severe forms of fluorosis in Prakasam district even though drinking water contains mostly 1 ppm to 3 ppm of fluoride and it rarely exceeds 6 ppm and the majority of cases investigated had kidney disease.
5. Presence of abnormal amounts of certain trace elements, such as strontium, arsenic, silica, uranium, chromium, etc. in drinking water supplies and foodstuffs also affect fluoride metabolism. Ninety-four drinking water samples from endemic areas in Andhra Pradesh were investigated for their content of fluoride and strontium. Fluoride levels ranged between 0.1 ppm and 9.5 ppm with a mean fluoride content of 2.1 ppm whereas strontium levels varied between 4.9 ppb and 9931.7 ppb with a mean of 1591.2 ppb. Strontium is a bone seeking element akin to calcium and fluoride which causes osteogenesis and bone changes similar to fluoride and now is the preferred drug for the treatment of post-menopausal osteoporosis. Arsenic is known to aggravate fluoride toxicity in experimental studies and this element may play a role in fluorosis in eastern parts of our country where arsenic is a known hazard. Silica, uranium and chromium are nephrotoxic if taken in abnormal amounts through water and these elements may be responsible for the high incidence of kidney disease in some endemic areas of India such as Prakasam.

AETIOPATHOGENESIS

In fluorosis, there is an overall increase in bone mass and calcification and ossification of ligaments and inter-osseous

fasciae along with periosteal new bone formation and development of exostoses on long bones and osteophytes on the spine. These changes in skeleton underlie the clinical manifestations of fluorosis.

CLINICAL FEATURES

Chronic fluoride intoxication presents an extraordinary degree of uniformity in its clinical manifestations. It occurs in humans as dental and skeletal fluorosis, since 96% to 99% of fluoride retained in the body combines with mineralised bones because of its affinity to calcium phosphate moiety, and hence, skeleton suffers. Dental and skeletal stages are separated by a prolonged, relatively symptom-free interval during which the skeleton does not stop accumulating fluoride. In its advanced stages, skeletal fluorosis causes crippling deformities and neurological complications.

Dental Fluorosis

Dental fluorosis mainly involves enamel but severe intoxication may affect dentine as well as pulp. Enamel fluorosis occurs when fluoride concentrations in or in the vicinity of the forming enamel are excessive during its pre-eruptive development. Mottling of teeth is one of the earliest and most easily recognisable features noticed in the first decade of life (**Figure 1**). Both sexes are equally affected. It is the permanent teeth that are affected and they lose their normal creamy white translucent colour and become rough, opaque and chalky white. Pitting and chipping are other marks of fluorosis. Brown, yellow or black pigment gets deposited on the defective enamel and once established tends to remain there permanently. Incidence of dental fluorosis in endemic areas exhibits a linear relationship to the fluoride content of water but it may also vary with other factors. Dental fluorosis does not obviously occur, when there has been no exposure to excess fluoride in the first decade of life.

Figure 1: Characteristic mottling of the teeth in dental fluorosis. Mottling is most conspicuous on the upper incisor teeth.

Pre-Skeletal Stage

The duration of this stage may vary with the amount of daily fluoride ingested. Reportedly, it ranges from 10 years to 30 years or even longer in endemic areas. It is usually free of any signs or symptoms in its early stages in endemic regions. However, various reports from Europe and America suggest that there would be symptoms corresponding to gastro-intestinal, musculoskeletal, respiratory and visceral systems during this stage. The majority of these visceral symptoms may be due to allergy to fluoride in susceptible individuals or the effect of fluoride on the various target organs and these are nonspecific.

Skeletal Fluorosis

Early in the development of fluorotic changes in the skeleton, the patients often complain of a vague discomfort and paraesthesia in the limbs and the trunk. Pain and stiffness in the back appear next, especially in the lumbar region, followed by dorsal and cervical spines. Restriction of the spine movements is the earliest clinical sign of skeletal fluorosis. The stiffness increases steadily until the entire spine becomes one continuous column of bone manifesting a condition referred to as 'poker back' (**Figure 2**). When the condition becomes severe and chronic, pathology spreads from axial skeleton to various joints in the limbs owing to the involvement of the joint capsules, the related ligaments, tendinous attachments to the bones and interosseous membranes. The involvement of the ribs gradually reduces the movement of the chest during breathing, which finally leads to restrictive lung disease. With the increasing immobilisation of the joints due to contractions, flexion deformities may develop at hips, knees and other joints, which make the patient bed-ridden (**Figure 3**).

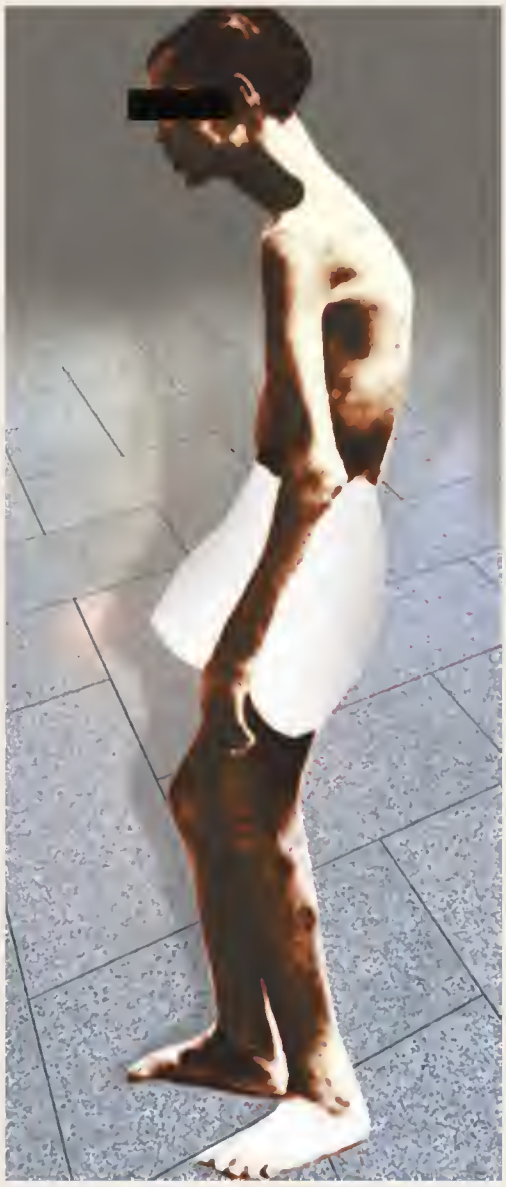

Figure 2: Skeletal fluorosis manifesting with restriction of spine movements, which ultimately leads to 'poker back'.

Figure 3: Crippling stage of skeletal fluorosis manifesting with neurological deficits and joint changes.

The stage at which skeletal fluorosis becomes crippling usually occurs between 30 and 50 years of age in the endemic regions. Newcomers to a hyperendemic region may sometimes develop symptoms of skeletal involvement within 4 years of their arrival. Men suffer more than women from severe affects of the disease presumably because their work usually more strenuous than that of women. In regions with very high fluoride content, the disease may affect younger age groups including children. The longer the exposure to fluoride higher will be its incidence.

Endemic Genu Valgum

Deformities occur most notably in weight-bearing lower limbs in children poorly nourished with low calcium intake in endemic areas. There is increased calcium turnover in the cases of endemic skeletal fluorosis. Diets poor in calcium provoke secondary hyperparathyroidism. This, in turn, leads to osteoporosis and deformities of weight-bearing lower limb bones (**Figure 4**).

Neurological Manifestations of Skeletal Fluorosis

The neurological sequelae in skeletal fluorosis manifesting usually as radiculomyelopathy arise principally because of the mechanical compression of the spinal cord and nerve roots brought about by osteophytosis and sclerosis of the vertebral column. But the neural toxicity attributable to fluorides is yet to be established.

Neurological complications arise at a late stage of the disease in about a tenth of the total number of skeletal fluorosis cases.

Figure 4: Gross deformities of lower limbs in the residents of Yellareddyguda of Nalgonda, India, which is high endemic village for fluorosis.

But there have been few reports of fluorosis with neurological complications from countries other than India.

The patients suffering from neurological manifestations varied in age from 20 to 70 years and, in the case of younger age groups, these complications may be traced to higher levels of daily fluoride ingestion. The men were reported to have been affected more frequently than the women. Similar findings were reported by other investigators from India, except for one lone report from Rajasthan where females slightly predominated over males and also developed fluorosis earlier than men.

It is the cervical cord rather than the dorsal cord that is commonly affected by fluorosis although, lumbar spine is usually the first to exhibit skeletal changes caused by fluorosis, compression of *cauda equina* rarely occurs because its roots are so easily accommodated that by the time these are pressed upon, other parts of the spinal cord would have been affected. Although the disease develops slowly but relentlessly, the neurological deficits may sometimes be precipitated by a minor trauma. Such cases present a wide spectrum of neurological deficits, which may be found manifesting either the lower motor neuron or the upper motor neuron defects or both, which is much more common. These may be found along with those caused by skeletal fluorosis resulting in restriction of spine movements. It is to be noted that in fluorosis abnormalities of higher functions of cerebrum or cranial nerve palsies except eighth nerve are rarely encountered.

Peripheral Neuropathies

Exostoses, which mainly develop around the knee, elbow and ankle, may press upon the median, ulnar or lateral popliteal nerves. Even meralgia paresthetica has been reported to occur in fluorosis. Fluorotic patients may also manifest entrapment syndromes involving other peripheral nerves.

DIAGNOSIS

Urinary, Serum and Bone Fluoride Estimations

Urinary fluoride levels are the best indicators of fluoride intake. Since fluoride excretion is not constant throughout the day, 24-hour samples of urine are more reliable than random or morning samples. There is a linear relationship between urinary fluoride levels and fluoride intake. The urinary and serum levels of fluoride in normal and fluorotic cases are listed in **Table 1** below.

Table 1: Serum and Urine Fluoride Levels in Healthy Adults and Patients of Fluorosis

Group	Number	Range	Mean
Serum fluoride levels		**mg/L/ppm**	**mg/L/ppm**
Healthy adults	500	0.03 to 0.13	0.08
Patients of fluorosis	17	0.04 to 0.28	0.16
Urine fluoride levels		**24-hr/mg/ppm**	**mg/L/ppm**
Healthy adults	60	0.38 to 1.82	0.88
Patients of fluorosis	17	0.68 to 7.80	3.28

Bone fluoride content measures the extent of bone fluoride retention and is a useful complement of bone histological studies for the diagnosis of skeletal fluorosis. In skeletal fluorosis, fluoride content varies between 6000 and 8400 ppm in bone ash, normal fluoride content ranges between 500 and 1000 ppm or mg/kg.

Radionuclide Bone Scan

Technetium labelled methylene diphosphonate (99mTc-MDP) bone scanning measures skeletal metabolism and in skeletal fluorosis shows mostly a super scan appearance and in some cases joints abnormalities (**Figure 5**).

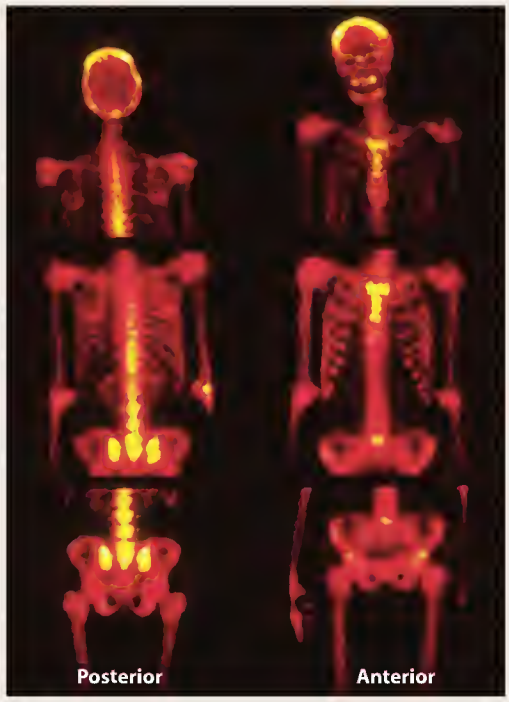

Figure 5: Technetium-99m scans of skeleton in an individual with skeletal fluorosis suggesting an appearance of 'super scan'. There is high bone turnover in endemic skeletal fluorosis with increased tracer uptake in axial and appendicular skeleton. There is reduced soft tissue uptake, absent renal images and 'tie sign' in the sternum. Increased metabolic turnover of bone, impaired collagen synthesis and increased avidity for calcium are the features of fluoride toxicity.

Radiology

In fluorosis, radiological findings closely parallel the pathological changes. In adults, the radiological findings can be categorised into three stages:

Stage I

Findings mainly confined to the axial skeleton, trabeculae appear rough and bone appears ground glass.

Stage II

Thick primary trabeculae merge with sclerotic secondary trabeculae to make bone homogenously dense, bone contours become uneven, calcification of paraspinous, sacrospinous and sacrotuberous ligaments.

Stage III

Axial skeletal bones demonstrate the typical radiological features. Calcification is marked at the insertion of muscles and tendons. Ossification of interosseous membranes of forearm bones is diagnostic sign of fluorosis (**Figure 6**).

Figure 6: Radiograph of forearm bones of a patient with fluorosis. The forearm bones are dense with calcification of a portion of interosseous membrane. Prominent bony tuberosities and musculotendinous attachments are noteworthy.

Osteosclerosis is well known effect of chronic fluoride intoxication, which can also manifest with osteoporosis and osteomalacia in endemic areas with poor nutrition. Hence, the radiological changes are varied and these seem to be dependent upon calcium intake by the individuals.

Imaging

Computed tomography (CT) is the best imaging modality for visualisation of bone pathology and provides more details than plain radiographs. The CT is better to visualise the direction of the osteophytes, a finding which may help in surgical planning. Spinal canal and root canal stenosis are also better appreciated with CT. The calcified ligaments are visualised with much more clarity and earlier than by plain radiograph, so are the indentations of the epidural space and the alterations in the spinal canal. By reconstruction, CT provides exact dimensions of the ossified intra-spinal ligaments, such as posterior longitudinal ligament and yellow ligaments.

Magnetic resonance imaging (MRI) being non-invasive obviates the difficulties in performing myelography and also delineates soft tissue structures and changes in the spinal cord. It is worthwhile to image the entire spine that may demonstrate

incidental pathological lesions peculiar to fluorosis. Fluorotic vertebrae are hypointense in both T1- and T2-weighted images and these are diagnostic (**Figure 7**).

Figure 7: Magnetic resonance imaging of dorsal spine. T1 (left) and T2 (right) weighted images demonstrating hypointense signal of the vertebral bodies suggestive of sclerosis in skeletal fluorosis, which is diagnostic. Note the cord compression at multiple levels from calcified ligamentum flavum.

DIFFERENTIAL DIAGNOSIS

In endemic areas, the diagnosis of dental and skeletal fluorosis does not present much of a problem. In industries, where fluoride toxicity is a known hazard, skeletal fluorosis marked by restriction of spine movements can easily be diagnosed. In early stages of skeletal fluorosis patients complain of arthritic symptoms, which have to be differentiated from other types of arthritis. Diseases that are associated with osteosclerosis also need to be considered in the differential diagnosis. In children and young adults, genu valgum and other deformities have to be distinguished from those associated with rickets and sometimes with osteodystrophies. When sclerosis of the vertebral column is not marked, calcification of the interosseous membrane of forearm, a radiographic sign of fluorosis, should suggest the diagnosis of fluorosis.

Endemic Fluorosis

In India over 50% of ground water sources have excess of fluoride and affect more than 150,000 villages. Potable water supply with permissible levels of fluoride though desirable cannot obviously be made available to the vast number of people neither can they be shifted from their area of domicile. Thus, there is a rationale to press into service water-purifying or defluoridation plants in those areas. Defluoridation plants are based on *Nalgonda method* of lime and alum and domestic units were based on filtration of fluoride-rich water with PAC granules, which are activated alumina. Aluminum has been incriminated in the causation of two neuro-degenerative diseases, namely Parkinsonism and amyotrophic lateral sclerosis. Defluoridation methods are expensive and difficult to maintain and they also increase aluminum levels of filtered water. Hence, these methods are not preferred. Nutrition appears to play a crucial role in the incidence and severity of fluorosis and hence a balanced diet having adequate calcium, magnesium and vitamin C should be promoted to reduce the toxicity of fluoride.

MEDICAL TREATMENT

Patients with skeletal fluorosis, when kept off fluoride intake, register a negative fluoride balance while continuing to excrete large amounts of fluorides for years. It is obvious that excretion of fluorides mobilised from the skeleton through urine and faeces is a very slow and prolonged process lasting for many months to even years. Hence, this method is not practicable.

Studies, both *in vitro* and *in vivo*, have been done to study the effect of various drugs on the binding of fluoride and also on the excretion of fluoride. Serpentine was used to increase fluoride excretion in human fluorosis with some success. Serpentine, a naturally occurring mineral, is chemically a magnesium meta silicate and has enormous capacity to absorb fluoride at a wide range of pH. There is a need to do long-term studies to see the effectiveness of these various agents in human fluorosis.

SURGERY IN SKELETAL FLUOROSIS

Neurological manifestations of fluorosis are mainly mechanical in nature. However, surgery is obviously of little help in the alleviation of neurological deficits in view of the extensive prevalence of the disease. Surgical decompression is only possible in such of those early cases in which the compression is confined to a limited segment of the vertebral column, but managing even these patients bristles with problems because of rigidity of spine and restrictive lung disease. However, in recent years with accurate localisation of the compression, its extent in both vertical and axial planes by imaging, fiberoptic intubation, better illumination and instrumentation during surgery for drilling and removal hard fluorotic bone and postoperative ventilatory support made surgery safe and effective in alleviation of mechanical compression in fluorosis. The results of surgery are better in the case of cervical and lumbar areas and poor in the case of dorsal cord compressions. It is also not known what happens to all those patients after surgery, when they go back to their endemic areas and again start to consume high-fluoride-containing water and food.

PREVENTION OF FLUOROSIS

The best approach to tackle this public health menace will be prevention since no cure is possible once the disease sets in.

26.11 Lathyrism

UK Misra, J Kalita

Lathyrism is a neurodegenerative disease characterised by spastic paraplegia following excessive consumption of the legume *Lathyrus sativus*. *Lathyrus sativus* forms the staple food of poor villagers, especially during the period of food scarcity following a flood or famine. Lathyrism has been reported from Asia, Africa and Europe. However, in recent years, it has only been reported from developing countries such as Bangladesh, Ethiopia, India and Nepal. In India, epidemics have been reported from Maharashtra, Madhya Pradesh (Satna and Rewa), Bihar, West Bengal and Uttar Pradesh (Unnao) with an incidence between 0.3% and 2.5%.

CURRENT STATUS OF LATHYRISM IN INDIA

Currently, lathyrism is not a major health problem in India, and hardly any patient have been reported after the last epidemic of lathyrism in Unnao (UP) in 1984. This is because of the ban on the trade of *L. sativus* seeds in India.

PATHOPHYSIOLOGY

L. sativus is known to contain a number of toxic amino acids. Intraperitoneal injection of an alcoholic extract of *L. sativus* produces opisthotonus and leg weakness in chicks. Two free amino acids, β-N-oxalylamino-L alanine (BOAA) and β diaminopropionic acid have been found to be toxic in animal models, such as rats, mice and monkeys. *L. sativus* treated monkeys also had prolongation of central motor conduction time. These results suggest pyramidal tract dysfunction following *L. sativus* or BOAA intoxication. The only autopsy report including the brain is of a patient who developed lathyrism 31 years prior to death. On brain histology, loss of giant Betz cells and shrinkage of pyramidal neurons in the pre-central gyrus were observed. The other studies reported spinal cord autopsy findings which include distal and symmetrical degeneration of lateral and central corticospinal tracts associated with degeneration of spinocerebellar tracts and tractus gracilis. In another patient, who developed lathyrism 31 years ago, some changes in anterior horn cells with swelling, Hirano bodies and dispersion of Nissl bodies were seen. In the absence of precise neuropathological studies including motor areas, it is not clear whether lathyrism primarily originates in the neurons or is a central distal axonopathy involving the pyramidal tracts. BOAA excitotoxic hypothesis suggests that molecular pathology of lathyrism could start at the neuronal level in motor cortex with secondary degeneration of pyramidal fibres in spinal cord. BOAA also produces seizures in experimental animals because it is a potent glutamate agonist. Glutamate also results in neuronal death when post-synaptic glutamate receptors are over stimulated for a long period. The concentration of BOAA in lathyrus plants varies from 0.1% to 1%. It has been suggested that BOAA could selectively inhibit the brain mitochondrial enzyme NADH dehydrogenase. In monkeys, pyramidal tract dysfunction has been produced by feeding *L. sativus* for 3 to 10 months or BOAA for 3 months. The affected monkeys develop tremors, myoclonic jerks and increased tone in the legs. Another non-protein amino acid of *L. sativus*, β-isoxazoline alanine (BIA) is also neurotoxic to neurons in culture, but to a lesser extent than BOAA. BOAA toxicity is more pronounced in younger animals compared to the older ones. Brain lesions are mainly observed in areas where blood brain barrier is normally absent.

CLINICAL FEATURES

Lathyrism affects adolescents and young adults who are otherwise healthy. Females, however, are less commonly affected. Lathyrism can present in 3 ways.

Sudden onset of leg weakness on getting up from sleep is the most common presentation; subacute onset of walking difficulty occurs in some patients or insidious progression of spastic paraplegia occurs rarely.

Majority of patients complain of leg stiffness, weakness and heaviness prior to the onset of paraparesis. Some patients may also complain of cramps and calf pain, unsteadiness, leg paraesthesia and urgency of micturition. On neurological examination, the patients have spastic paraplegia, scissoring gait, exaggerated knee and ankle reflexes and extensor plantar response. Crossed adductor reflex and patellar and ankle clonus may also be present. Cranial nerves, cerebellar functions and sensations are normal. Upper limbs are also normal. Associated peripheral neuropathy has been reported from Bangladesh and lower motor neuron signs from Israel, but these are not found in our experience.

The disability in lathyrism is graded according to the need for help for walking. Most patients walk slowly without the need of a stick (no stick stage), while others need one or two sticks (one or two stick stage) and those crawling on hands and knees (Crawler stage) (**Figure 1**).

Non-invasive transcranial motor stimulation studies have been employed to evaluate the conduction in motor pathways. Central motor conduction time to lower limbs in lathyrism reveals mild to moderate slowing in majority of patients. Occasionally, central motor conduction time may be normal or even markedly prolonged. These results are consistent with the wide spectrum of involvement of motor pathways. Somatosensory evoked potentials are normal which is consistent with normal sensations in lathyrism.

DIAGNOSIS

The diagnosis of lathyrism is based on the typical clinical findings and history of consumption of *L. sativus*. There are no specific laboratory tests. The patients of lathyrism should

Figure 1: Different stages of clinical severity of lathyrism.

be differentiated from primary lateral sclerosis, hereditary spastic paraplegia, nutritional myelopathy, early spinal cord compression, HTLV myelopathy and multiple sclerosis, especially in an endemic area.

TREATMENT

Treatment includes elimination of *L. sativus* from the diet in all cases. This may result in improvement in some patients, but in majority, the spasticity persists. Symptomatic relief may be obtained by antispasticity drugs such as baclofen, tizanidine and diazepam. Physiotherapy may also help. Botulinum toxin has been tried, but cost limits its use.

For preventing lathyrism, cultivation and trade of *L. sativus* should be discouraged and alternative cultivation such as rice and wheat should be encouraged. Giving food aid of grains and pulses will stop the people from consuming *L. sativus*. The toxicity of *L. sativus* can be reduced by soaking it for 24 hours and repeated changing of the soaking water.

26.12 Epidemic Dropsy

Navneet Sharma

DEFINITION AND EPIDEMIOLOGY

Dropsy (from Hydropsy) is the description referring to a collection of serous fluid in all or any of the body's cavities or in the meshes of its tissue. Epidemic dropsy is the condition characterised by extensive progressive oedema of the legs caused by the ingestion of mustard oil (cooking media) derived from mustard seeds (*Sinapis albae*) contaminated with seeds of the plant *Argemone mexicana*. *Argemone mexicana* normally grows as a weed in many parts of India, the seeds of which resemble brown mustard seeds that contaminate the mustard oil with toxic alkaloids of the benzophenanthridine group.

The first record of epidemic dropsy was from the state of Calcutta in the year 1877 and since then numerous outbreaks of this condition have occurred in different parts of India. In the latest Delhi epidemic in 1999, there were 60 casualties and 3,000 victims had to be hospitalised. In 2002, another outbreak of epidemic dropsy occurred in Uttar Pradesh affecting 21 individuals.

AETIOPATHOGENESIS AND CLINICAL FEATURES

For clinical features of epidemic dropsy to develop, the estimated level of contamination of edible mustard oil with *Argemone* oil is ~0.5% to 1%. The route of exposure, aetiopathogenesis and clinical features are shown in **Figure 1**. The toxic alkaloids in *Argemone* oil cause an increase in permeability of blood vessels in different organs, i.e. heart, skin, liver, lungs, kidneys and eyes. Ocular manifestations occur in 12% cases and gastrointestinal symptoms in 52% to 84% of cases. Death has been reported due to cardiac and respiratory failure in 5% of cases. In 25% cases, oedema persists beyond 2 months and in 10% beyond 5 months.

LABORATORY ABNORMALITIES

Anaemia, leucopaenia and thrombocytopaenia have been reported. Anaemia is often normocytic normochromic. Mild impairment of renal and hepatic functions is present. Hypoalbuminaemia is a universal finding and combined respiratory alkalosis and metabolic acidosis is also present along with restrictive pulmonary ventilation defects. The chest radiograph may reveal pleural effusion, pulmonary oedema or pneumonia. Echocardiography is characteristically normal suggesting noncardiogenic pulmonary oedema as the cause for breathlessness.

DIAGNOSIS

It is usually straightforward when a history of contaminated oil use is forthcoming. In sporadic cases, a high index of suspicion is necessary for the diagnosis. The nitric acid test can be done easily at bedside on oil samples to detect contamination, but quantitative demonstration of alkaloids requires HPLC (detects 0.001% contamination by *Argemone* oil).

TREATMENT

Patients can present to the emergency department with pulmonary oedema. General measures recommended are: bed

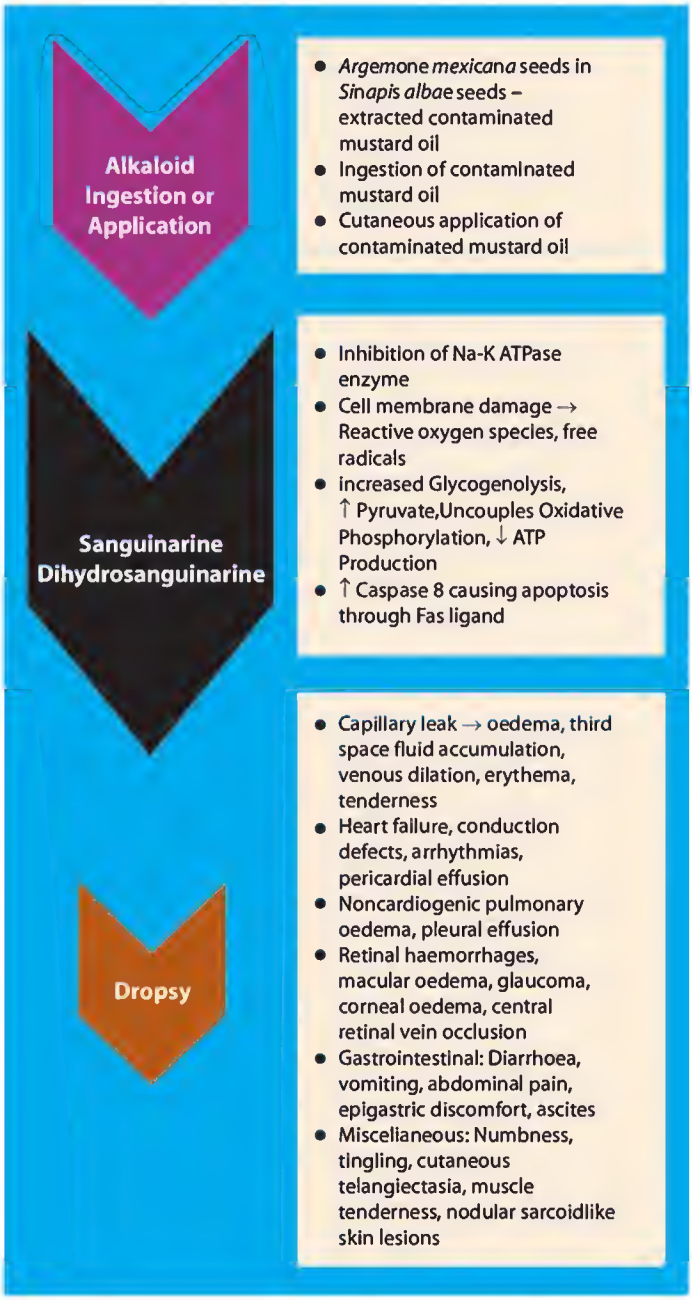

Figure 1: The aetiopathogenesis and clinical features of epidemic dropsy.

rest, oxygen inhalation, salt and fluid restriction, inotropic agents for hypotension and diuretics. For type 1 respiratory failure, non-invasive ventilation (NIV) is a promising treatment modality. Antioxidants like vitamin E and C and vitamin B complex although used have little evidence to support their use. Although, ACE-inhibitors, ARB's and aldosterone antagonists can be used for managing congestive heart failure (CHF), yet, their use has not been validated. Glaucoma is managed medically, but may need surgical intervention and follow-up with opthalmological services.

PREVENTIVE MEASURES

Mustard oil that is marketed should be subjected to rigid quality control measures to detect contamination and if found so, withdrawl from the markets.

26.13 Heavy Metal Poisoning

Praveen Aggarwal

INTRODUCTION

Patients with heavy metal poisoning generally present with multi-system involvement producing gastrointestinal, cardiovascular, neurologic and renal effects. The most common heavy metals and their compounds producing poisoning are mercury, lead, arsenic, antimony, cadmium, bismuth and thallium. Of these, poisoning with mercury, lead, arsenic, copper and thallium are of great concern to the general public and the medical community. The present Chapter will deal with the toxicology of these heavy metals.

ARSENIC

Arsenic is widespread geologically and exists in elemental, organic and inorganic (trivalent and pentavalent) forms with each of them having different toxicities. Arsine gas is the most toxic, followed by trivalent arsenic compounds (e.g. sodium arsenite, arsenic trioxide, potassium arsenite). Pentavalent inorganic arsenicals (e.g. lead arsenate, arsenic acid, calcium arsenate) are less soluble and less toxic. Elemental arsenic is considered to be nontoxic. Most of the organic arsenic compounds (melarsoprol, arsanilic acid) are less toxic than inorganic arsenic salts. Seafood contains arsenic in the form of organoarsenicals (e.g. arsenocholine and arsenobetaine), which are nontoxic.

Sources of Exposure

Arsenic is used in the manufacture of pesticides and rodenticides in the agricultural industry. It is widely used in timber preservatives, termicides, herbicides, glass production, specialised alloys and pigments. In many parts of the world, arsenic is a natural contaminant of ground waters. Sodium arsenate is used as an ant-killer. Fowler's solution, which was used in the treatment of psoriasis, contains 1% potassium arsenate. Melarsoprol is used to treat trypanosomiasis. Arsenic trioxide is occasionally used in the treatment of relapsed acute promyelocytic leukaemia. Arsenic toxicity can occur when arsenic-containing solutions are exposed to acids.

Arsenic Poisoning in India

A number of cases of chronic arsenic poisoning due to drinking of contaminated underground water have been reported from West Bengal. The maximum permissible limit recommended in the absence of an alternative source of potable water in the affected areas by the World Health Organization (WHO) in groundwater is 10 µg/L. However, in India, the accepted level is below 50 µg/L. The levels are higher than 50 µg/L in several districts of West Bengal. More than 40 million people live in the arsenic-affected region of the state. It is suspected that about 5 million people drink arsenic-contaminated water in West Bengal. Recent reports indicate the propensity of arsenicosis affecting other states in the Ganga/Brahmaputra plains too. Northeastern states; Bihar, Jharkhand, Uttar Pradesh, Andhra Pradesh and Chhattisgarh are also reported to be in the grip of this deadly disease. This makes it one of the world's worst calamities in recent times.

Mechanism of Toxicity

Both inorganic and organic arsenic salts may be absorbed after oral ingestion. However, because of low solubility, many pentavalent arsenic compounds are excreted in the stool before dissolution. Arsine gas is very rapidly absorbed from lungs. Trivalent arsenic compounds inhibit pyruvate dehydrogenase complex via inhibition of sulfhydryl group-containing cellular enzymes, which results in reduced citric acid cycle activity and reduced gluconeogenesis. Pentavalent arsenic produces toxicity by converting into trivalent arsenic. In addition, pentavalent arsenic produces toxicity by uncoupling oxidative phosphorylation resulting in ineffective generation of adenosine triphosphate. Arsine becomes localised in the red blood cell, which results in rapid and often severe haemolysis.

Another postulated mechanism for toxicity produced by various heavy metals, including arsenic, lead and mercury, is generation of reactive free radicals, which produce cellular damage, depletion of enzyme activities, damage to lipid bilayer and DNA.

Clinical Features

Although as little as 1 mg of arsenious oxide can produce acute toxicity, doses in the range of 20 mg of arsenic in adults are often associated with severe symptoms. The lethal dose has been estimated at 200 mg to 300 mg. Exposure to large doses produces acute toxicity while exposure to substantially lower amounts over a period of time will result in chronic toxicity.

Arsine gas poisoning

Initial symptoms of acute arsine poisoning are generally vague and include headache, weakness, nausea, vomiting and abdominal pain. Within a few hours, the patient develops intravascular haemolysis leading to jaundice, haemoglobinuria and acute renal failure.

Acute arsenic poisoning

The symptoms of acute intoxication may be evident within minutes of arsenic ingestion or may be delayed for several hours if food is present in the stomach. Acute exposure leads to vomiting, watery (may have 'rice water' appearance), and later bloody stools and severe abdominal pain. This can result in electrolyte imbalance, hypotension and shock. Cardiotoxicity manifests as altered myocardial function, electrocardiogram (ECG) changes (prolongation of QT interval and abnormal T-waves) and arrhythmias. Acute encephalopathy can develop and progress over several days and results in delirium, coma and convulsions. Occasionally, peripheral neuropathy with a glove and stocking distribution may occur acutely. Other features include acute respiratory distress syndrome, hepatitis,

haemolytic anaemia and rhabdomyolysis. Acute renal failure may develop due to fluid loss, myoglobinuria, haemoglobinuria or direct renal toxicity. Fever may develop in a few patients. A garlic-like odour of breath may help in diagnosing arsenic poisoning. Fatalities occur within one to four days due to cardiovascular collapse.

Patients who have been poisoned acutely with lower amounts of arsenic develop less severe manifestations, which include gastroenteritis that may continue for several days.

Following acute intoxication, patients often develop additional features. Peripheral sensorimotor neuropathy typically develops in 1 to 3 weeks. This may mimic Guillain-Barré syndrome. Encephalopathic features include headache, drowsiness, reduced memory, hallucinations and seizures. A few patients develop haemoptysis and patchy infiltrates in the lungs. Skin manifestations are alopaecia, oral lesions and macular rash. Mees' lines [transverse white bands (1 to 2 mm wide) on the nails] may develop but are uncommon. Similar lines have also been described in thallium, lead poisoning, Hodgkin's disease and renal failure.

Chronic arsenic poisoning

Arsenicosis has been defined by the WHO working group as a chronic health condition arising from prolonged ingestion (not less than 6 months) of arsenic above a safe dose, usually manifested by characteristic skin lesions, with or without involvement of internal organs.

Chronic exposure to arsenic produces muscle weakness, myalgias, abdominal pain, and excessive salivation and lacrimation. Typical manifestations of chronic arsenic poisoning include pruritus, hyperpigmentation or less commonly, hypopigmentation of skin with a 'raindrop' pattern and thickening (hyperkeratosis) of palms and soles, which sometimes may show nodularity (**Figure 1**). Sometimes, macular areas of depigmentation may appear on normal skin or hyperpigmented background producing the distinctive appearance of 'leucomelanosis'.

Symmetrical peripheral neuropathy, involving both sensory and motor neurons, is common and the patient presents with paraesthesias, numbness, pain and muscular weakness of the extremities. The neuropathy is generally axonal and preferentially affects the large fibres.

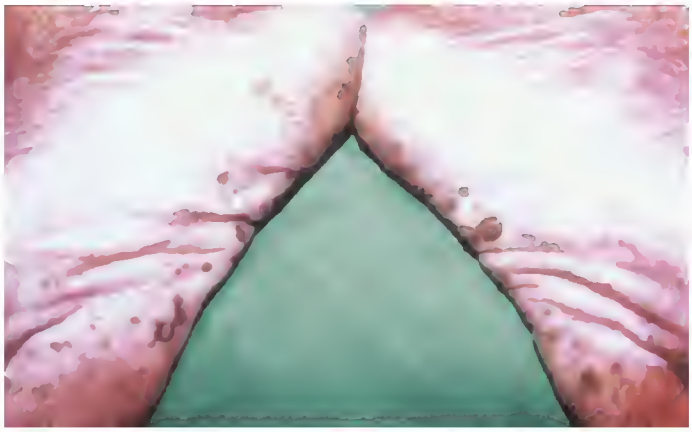

Figure 1: Photograph showing nodular hyperkeratosis of soles in a patient with chronic arsenic poisoning.
Courtesy: Dr M Romom, All Indio Institute of Medicol Sciences, New Delhi.

Haematological abnormalities include varying degrees of anaemia, leucopenia and thrombocytopaenia. Anaemia is most commonly normocytic and normochromic. Basophilic stippling may be seen.

Cardiovascular features include conduction abnormalities and prolongation of QT interval. Acrocyanosis and Raynaud's phenomenon occur occasionally and may progress to endarteritis and frank gangrene of the extremities (black-foot disease).

Chronic exposure to arsenic may lead to hepatomegaly and non-cirrhotic portal hypertension. Other uncommon features include development of diabetes mellitus and restrictive lung disease. Arsenic has been classified as a carcinogen and the patients may develop Bowen's disease, squamous and basal cell carcinomas of skin and lung and bladder carcinomas. Arsenic poisoning has also been shown to cause immunosuppression.

Table 1 lists some of the common clinical features of chronic arsenic poisoning.

Table 1: Clinical Features of Chronic Arsenic Poisoning

Cutaneous	Melanosis: Fine freckled or spotted pigmentation (raindrop pigmentation); diffuse hyperpigmentation; guttate hypopigmentation on normal or hyperpigmented background (leucomelanosis) Hyperkeratosis: Keratotic papules with thickening of palms and soles Malignant/Pre-malignant lesions: Bowen's disease, squamous cell carcinoma, basal cell carcinoma
Neurological	Peripheral neuropathy: Predominantly sensory
Peripheral vascular disease	Raynaud's phenomenon, claudication, gangrene (black-foot disease)
Respiratory	Chronic bronchitis, pulmonary fibrosis, bronchiectasis
Hepatic	Non-cirrhotic portal fibrosis, cirrhosis of liver, portal hypertension
Gastrointestinal	Anorexia, nausea, chronic diarrhoea
Haematological	Anaemia, leucopaenia, thrombocytopaenia

Diagnosis

Arsenic is radio-opaque and an abdominal radiograph may reveal a radio-opaque substance in the gut. However, it is rapidly absorbed from the gastrointestinal tract and radiographs taken in cases of known arsenic ingestions are usually negative.

Blood levels of arsenic are not of much use in diagnosing poisoning. Urinary arsenic levels are required to make a definitive diagnosis of arsenic exposure. Excretion of arsenic of more than 100 µg in 24 hours or 50 µg/L is abnormal. The urine specimen should be collected in a metal-free container. Since most laboratories measure total urinary arsenic, patients should be told to avoid seafood for at least 3 days prior to urine collection. Arsenic levels in hair and nails are also useful in diagnosis of chronic poisoning (normal arsenic levels in hair and nails are below 0.5 mg/kg and 1 mg/kg, respectively). A single dose of arsenic can be detected at the distal tip of the nails about 100 days after the exposure.

Treatment

Treatment of acute arsenic poisoning should include decontamination, chelation and supportive care. Since profuse vomiting is a common early symptom, gastric lavage may not

be necessary, but should be considered in every case. Whole bowel irrigation is another option for decontamination. Since activated charcoal does not adsorb arsenic, its role is limited to unknown ingestions. Intravenous fluids are frequently necessary to assure adequate intravascular volume. Electrolytes must be monitored and imbalances corrected when necessary. Glucose levels and glycogen stores should be maintained by parenteral administration of dextrose. Treatment of cardiotoxicity may require vasopressors. Haemodialysis may be indicated for renal failure; however, it does not remove significant amount of arsenic and is not indicated if renal function is normal.

The chelation therapy in acute arsenic toxicity consists of dimercaprol (British anti-Lewisite) and should be started immediately in suspected acute poisoning before laboratory confirmation. However, there is some evidence that BAL may increase arsenic transport into brain. It is available in vials containing 3 ml solution with 100 mg BAL/ml. It should be administered by deep intramuscular injection. Dimercaptosuccinic acid (DMSA) and dimercapto-1-propane sulphonate (DMPS) appear to be better alternatives than BAL in most patients who are not critically ill. The DMPS is administered in a dose of 5 mg/kg intravenously every 4 hours till the patient can be able to tolerate the medication orally. The oral dose in adults is 400 mg every 4 hours for a week. The recommended dose of DMSA is 10 mg/kg every 8 hours for 5 days and then 10 mg/kg every 12 hourly. D-penicillamine has not been shown to be efficacious in patients with arsenic poisoning.

Chelating agents have frequently been considered for treatment of chronic arsenic toxicity and arsine toxicity; however, their usefulness is yet to be established. The only treatment presently available for arsine poisoning is exchange transfusion or haemodialysis if renal failure develops.

LEAD

Lead is ubiquitous in the environment but has no physiologic role in our biological systems. It exits in elemental form (e.g. bullets), as well as in inorganic and organic forms. Inorganic lead compounds include lead oxide, lead chromate, calcium plumbate and lead sulphide. Tetraethyl lead, the anti-knock compound added to gasoline, is an organic lead compound.

Sources of Exposure

Lead is a persistent metal that is present in the environment (in water, soil and dust). **Table 2** gives common sources of lead exposure.

Table 2: Common Sources of Lead

Paint (lead-based)
Household dust
Lead water pipes
Soil around the home
Herbal and traditional remedies
Food-storage articles: Lead-glazed ceramic ware, lead crystals and lead-soldered cans
Paint on children's toys
Industrial: Smelting, soldering, battery making, ship building, glass manufacture

The most common sources of inorganic lead exposure include paints and lead-contaminated soil. Lead-based paints are still widely used in developing countries. Lead pigments (usually lead carbonate) account for as much as 50% of many white household paints and a thumbnail-sized chip of this paint may contain as high as 200 mg of lead. Lead-based paints have also been used in toys. Studies from India have reported lead levels within permissible limits as well below 600 ppm in latex paints but the levels have been found to be high (upto 1,40,000 ppm) in most samples of enamel paints. Among the enamel paints, white paints have been found to have the lowest concentration of lead while yellow and orange with the highest concentration. More than 30% samples of floor dust in Delhi homes have been shown to contain excessive lead.

Drinking water is also a major source of lead exposure as leaded plumbing components continue to be used in water pipes. Food storage articles like lead-glazed ceramic ware, lead crystals and lead-soldered cans may contain significant amount of lead.

Industries classically associated with lead exposure include smelting, battery making, ship building and glass manufacture. Automotive and industrial emissions are the major contributors to lead in air. Use of lead-free petrol has reduced lead toxicity produced by automotive emission to a large extent and has resulted in marked reduction in lead levels among children in developed nations as well as in India. Chronic sniffing of petrol may produce lead poisoning. Recycling of automobile batteries is another source of lead exposure.

Surma (kohl, kajal) has also been reported to produce lead encephalopathy in children. Many samples of *surma* contain as much as 88% of lead sulphide. *Sindoor* contains a high amount of lead (roughly 57% by weight) and may produce lead toxicity if used as food-colouring agent. Many herbal preparations may contain significant amounts of heavy metals with lead content ranging from 5 µg/g to 37,000 µg/g.

Another source of lead is the consumption of illicit liquor which is contaminated by lead (moon shine). Swallowing foreign bodies containing lead and retained lead bullets in joints have been linked to chronic poisoning.

Mechanism of Toxicity

The amount of inorganic lead absorbed through gut is about 10% to 15% of the ingested quantity; for pregnant women and young children, the amount can increase upto 50%. The absorption of lead is enhanced if the diet is deficient in iron, calcium and zinc. Approximately 30% to 40% of inhaled lead is absorbed into the blood-stream. Inorganic lead is minimally absorbed through the skin, but tetraethyl lead (leaded gasoline) is well absorbed through skin.

Once absorbed, 99% of circulating lead is bound to erythrocytes for approximately 30 to 35 days and is dispersed into the soft tissues over the following 4 to 6 weeks. Lead is stored in bones for up to 30 years. When bone metabolism increases (e.g. during pregnancy and lactation, fracture healing and chelation therapy), stored lead leaves the bone and re-enters the circulation and can increase the risk of lead toxicity. It can also expose the foetus to lead if mother had lead exposure previously.

Lead poisoning is also known as *saturnism* or *plumbism*. Lead forms complexes with sulphur, nitrogen and oxygen, and exerts its toxic effects by combining with sulfhydryl groups in proteins,

thus inhibiting sulfhydryl-dependent enzymes. It may act as an inhibitor or agonist of calcium-dependent processes. Lead inhibits several steps in haeme synthesis. It inhibits D-aminolevulinic acid dehydratase, producing increased levels of delta-aminolevulinic acid (ALA) in blood and urine. Several studies have shown that accumulation of ALA induces reactive oxygen species generation, which produces oxidative damage. Lead also inhibits coproporphyrinogen oxidase and ferrochelatase causing increased urinary coproporphyrin III and erythrocyte protoporphyrin concentrations, respectively.

Lead also interferes with excitatory neurotransmission by glutamate, which is the transmitter at more than half the synapses in the brain and is critical for learning. N-methyl-D-aspartate receptor is blocked selectively by lead. This compromises permanent retention of newly learned information. It is thought that lead affects the renin-angiotensin system, causing hypertension.

Clinical Features

Acute lead poisoning

The symptoms of lead toxicity are often vague and may arise acutely, even though the poisoning is usually chronic. Acute lead poisoning is uncommon. It can result from inhalation of large quantities of lead. In children, ingestion of large oral dose from various sources can produce acute poisoning. It can also occur in children with pica. Characteristics of acute poisoning are abdominal colic, constipation, fatigue, anaemia, renal failure, peripheral neuropathy, renal insufficiency, and in severe cases, encephalopathy (coma, convulsions, papilloedema). Vomiting is common in children. Neuropathy is generally of pure motor type resulting in foot and wrist drop.

Chronic lead poisoning

The important clinical symptoms and signs of chronic lead poisoning are given in **Table 3**.

Chronic lead poisoning in children

Chronic lead toxicity is more common, and in children, presents with pallor, underweight, short stature, loss of appetite, intermittent vomiting, constipation, headache and neuropsychological disturbances (irritability, nervousness, tremors, intermittent lethargy). Features compatible with lead encephalopathy include drowsiness, irritability, seizures, gait disturbances, evidence of increased intracranial tension and coma and can occur if exposure to lead continues. The probability of developing encephalopathy increases with rising lead levels and becomes significant when the levels exceed 70 µg/dL. Clinically important colic, peripheral neuropathy and chronic renal disease are uncommon in children as compared to adults.

Chronic lead poisoning in adults

Adults often present with abdominal colics, anaemia, hypertension and peripheral motor neuropathy. Renal toxicity has been well documented in occupationally exposed workers and it manifests as proximal tubular damage, glomerular sclerosis and interstitial fibrosis. Presentation may include proteinuria, impaired transport of glucose and organic anions and tubulointerstitial nephritis with or without renal failure. It can also precipitate gout (lead-induced gout or saturnine gout). Encephalopathy is rare in adults but neuropsychiatric features may develop. Occasionally, patients may develop lead line or Burton's line, which is a grayish-black line, at the junction of teeth and gums. It develops due to deposition of lead sulphide pigment formed by the lead molecules reacting with hydrogen sulphide in the oral cavity. There is an association between elevated blood lead levels and higher risk of amyotrophic lateral sclerosis.

Table 3: Clinical Features of Lead Poisoning

Apparently asymptomatic (lowest exposure; blood lead levels may be below 10 µg/dL)
Reduced learning and memory
Lowered IQ
Impaired speech
Hyperactivity
Low exposure
Myalgia
Paraesthesia
Fatigue/lethargy
Irritability
Mild abdominal discomfort
Change in taste
Moderate exposure (additional features)
Arthralgias
Inability to concentrate
Short-term memory loss
Tremor
Headache
Diffuse abdominal pain
Vomiting
Constipation
Hypertension
High exposure
Abdominal colic
Paresis or paralysis (wrist and foot drop)
Papilloedema
Somnolence, coma
Seizures
Lead line on gingival tissue (Burton's line)

Chronic petrol sniffing

Tetraethyl lead and its metabolites are highly neurotoxic. The clinical features vary from nonspecific symptoms, such as loss of appetite, lethargy and irritability, to altered mental status, psychosis, tremors, ataxia, myoclonus, chorea and seizures. Some of these features may be related to the associated toxic aromatic hydrocarbons contained in petrol. In the case of severe exposure, death may occur within a few hours or may be delayed for several weeks. Anaemia is uncommon with organic lead exposure.

Elevated lead levels in pregnancy

Elevated blood lead levels during pregnancy are associated with an increased risk of preterm births and can increase the risk of spontaneous abortion. The first pregnancy carries the greatest risk of lead toxicity. Blood lead levels may actually increase in women during pregnancy as a result of increased mobilisation of lead from bones into the blood. Lead freely crosses the placenta, and there is a strong correlation between maternal and umbilical cord blood lead levels. Because of incomplete blood-brain barrier, the effect of lead on the foetus's central nervous system is greater during gestation and in the first 3 years of life than in later life. The effects of lead exposure on the

foetus during gestation may be manifested after birth by low performance on cognitive tests. However, it is still unclear if lead is a teratogen.

Subclinical effects

Recent studies evaluating the relationship between blood lead levels and neurobehavioural performance have shown the evidence of effect at levels below 10 µg/dL – the current level considered excessive for children. At low-level exposure to lead, subclinical effects on central nervous system are the most common effects seen in children. As blood lead concentration increases by 10 µg/dL, the intelligence quotient decreases by 2 to 3 points. The child may become inattentive, hyperactive and disorganised. Delinquency is seen as the child grows. There is no evidence that chelation will reverse cognitive impairment.

Diagnosis

Measurement of blood lead levels is the standard screening test for lead toxicity. There is no toxic threshold for lead, i.e. there is no measurable level of lead in the body below which no harm occurs. For diagnostic purpose, blood lead levels above 10 µg/dL are considered abnormal although some neurological damage may occur even at lower levels. Blood lead level is only a reflection of recent or continued lead exposure and does not adequately reflect past exposure or accumulated bone lead levels.

In case of acute ingestion, abdominal radiograph may show radio-opaque lead chips. A normocytic anaemia with basophilic stippling of the red blood cells and abnormal liver function results are characteristics of lead poisoning. However, basophilic stippling and anaemia only occur after significant levels of exposure; at blood lead levels over 50 µg/dL in adults and 25 to 40 µg/dL in children. The urine may show protein and glucose.

Lead lines are dense transverse bands at the metaphyses of long bones. These lines generally develop after months of exposure. Since laboratory analysis of lead levels cannot be readily performed, children with unexplained encephalopathy should undergo radiography of the knees to look for dense metaphyseal band.

Measurement of erythrocyte protoporphyrin (EP) was used as an inexpensive screening test during 1970s. However, it is no longer recommended as it usually does not rise unless blood lead levels are above 25 to 35 µg/dL. Further, it may be elevated in iron deficiency states, porphyria, cirrhosis of liver and alcoholism. The EP assays may still be used if facilities to estimate blood lead levels are unavailable. The threshold for EP is 30 µg/dL. Similarly, calcium disodium edetate mobilisation test, which was used to assess lead excretion after a single dose of edetate, is not recommended at present.

Cortical bone lead measured by radiographic fluoroscopy, is considered a sensitive biomarker for cumulative lead exposure and correlates well with historical rather than current blood lead level measurements.

Treatment

Treatment of lead toxicity involves prevention of further exposure, decontamination, supportive care and chelation. Lavage should be used for recent ingestions. Whole bowel irrigation is recommended for ingestion of lead-containing foreign bodies. It is generally not indicated for lead paint chips. Activated charcoal does not bind lead. Seizures from lead encephalopathy may be resistant to benzodiazepines and phenobarbital; in such cases, measures to reduce intracranial pressure (mannitol, steroids, hyperventilation) are recommended. The options for symptomatic treatment of abdominal cramps are limited because these symptoms do not respond well to relaxants or analgesics. In patients with pronounced anaemia, transfusion may become necessary.

Dietary advice includes adequate intake of iron, calcium and vitamin C. Adequate iron and calcium stores may decrease lead absorption and vitamin C may increase renal excretion. The current recommendations for the management of children and adults with high lead levels are given in **Tables 4 and 5**.

Table 4: Treatment of Lead Poisoning in Children

Blood Level	Treatment
<10 µg/dL	No intervention
10 to 14 µg/dL	Lead education (dietary, environmental) Monitor lead levels every 3 to 6 months Correct iron deficiency, if any
15 to 19 µg/dL	Lead education (dietary, environmental) Monitor lead levels every 3 to 6 months Proceed according to actions for next category, if: Blood lead level increases or Blood level remains in this range in follow-up sample
20 to 44 µg/dL	Lead education (dietary, environmental) Monitor lead levels every 1 month Complete history and examination Laboratory work-up Haemoglobulin Iron status Correct iron deficiency, if exists Environmental investigation Abdominal radiograph if lead ingestion suspected
45 to 69 µg/dL	Same actions as listed above Administer chelation therapy with DMSA or $CaNa_2EDTA$
≥70 µg/dL	Hospitalise and start therapy with BAL and $CaNa_2EDTA$ Proceed according to actions for 45 to 69 µg/dL

Table 5: Treatment of Lead Poisoning in Adults

Blood Level	Treatment
<30 µg/dL	No treatment required
30 to 40 µg/dL	Monitor lead levels every 6 months Remove the source of exposure Screen for iron deficiency; administer iron if required
41 to 60 µg/dL	Monitor lead levels every 2 months until two consecutive levels are below 40 µg/dL Remove the source of exposure
>60 µg/dL	If symptomatic, administer $CaNa_2EDTA$ or DMSA If encephalopathy present, give BAL and $CaNa_2EDTA$ If asymptomatic, remove from source of exposure and monitor lead levels every month
>80 µg/dL	Start treatment with $CaNa_2EDTA$ or DMSA If encephalopathy present, give BAL and $CaNa_2EDTA$

Chelation therapy

The current recommendation is to use a combination of intramuscular BAL and intravenous calcium disodium edetate ($CaNa_2EDTA$) if blood lead levels are above 70 μg/dL in children or 100 μg/dL in adults. Unlike EDTA, BAL chelates lead from the brain also. An initial dose 50 mg/m² of BAL is given by deep intramuscular injection and 4 hours later, $CaNa_2EDTA$ 1000 mg/m²/day is begun via continuous intravenous infusion. The BAL is then continued simultaneously at a dose of 300 mg/m²/day in divided doses for every 4 hours. If encephalopathy is present, the daily doses of BAL and $CaNa_2EDTA$ are 450 mg/m² and 1500 mg/m², respectively. The treatment is given for 5 days. Courses of $CaNa_2EDTA$ can be repeated every 2 to 5 days.

Dimercaptosuccinic acid (DMSA) or succimer is effective in both children and adults. It is recommended if blood lead levels are 45 to 69 μg/dL in children or 70 to 100 μg/dL in adults, provided serious features including encephalopathy are not present. In contrast to BAL, DMSA is a more specific chelator of lead, arsenic and mercury while sparing essential metals such as zinc, calcium, copper, magnesium and iron. It is administered in a dose of 10 mg/kg every 8 hours for five days followed by 10 mg/kg every 12 hours for another 14 to 21 days. An alternative is to give repeated courses of 10 mg/kg every 8 hours for 5 days with a gap of 1 to 2 weeks between the courses. The length of course may be tailored to individual patient's response as indicated by the assessment of blood lead concentration.

Oral DMSA and parenteral $CaNa_2EDTA$ are both effective chelators of lead. There is currently insufficient data, however, to conclude that either antidote is superior in enhancing lead excretion. Both antidotes resolve the symptoms of moderate and severe lead toxicity rapidly. In tetraethyl lead, chelator therapy is almost completely ineffective.

D-penicillamine has also been used for lead poisoning. The usual dose is 25 to 40 mg/kg in four divided doses a day for 1 to 6 months. The adult dose is 1 to 1.5 g/day. The drug should be taken on an empty stomach. It may be useful in mild lead poisoning or when unacceptable adverse effects to both edetate and DMSA have occurred.

Various chelating agents useful in heavy metal poisoning are given in **Table 6**.

Antioxidants

Antioxidant molecules are thought to play a crucial role in counteracting free radical induced damage to macromolecules and have been found to heel the free radical mediated cell damage. Antioxidants like vitamin E, vitamin C, β-carotene and α-lipoic acid have been shown to be beneficial in studies conducted on animals with heavy metal poisoning.

MERCURY

Mercury occurs geologically in its elemental state and as inorganic salts (e.g. mercuric chloride, mercuric iodide, mercuric oxide, mercuric sulphide, mercurous chloride) and organic salts (e.g. ethylmercury, methylmercury, merbromin, phenylmercurial salts). Elemental mercury readily volatises at standard temperature (0°C) and its presence in an open container can result in significant air concentrations in unventilated or poorly ventilated spaces.

Sources of Exposure

Mercury is used in the manufacture of batteries, latex paint, urethane, polyvinyl chloride, scientific instruments and fungicides. It is also used in gold mining and refining and electrical industry. Organic salts such as merbromin and nitromersol are still used widely as topical antiseptics. Organomercurials have been used in human and veterinary medicines as an antiseptic, but the widest use has been in agricultural fungicides. Calomel (mercurous chloride) was used extensively in medicines. It is still being used in some creams and laxatives. Thiomersal, a long-chain alkyl mercury compound is widely used as a preservative in pharmaceutical industry. Some of the herbal medicines also contain inorganic mercury. Mercury-containing disc batteries may lead to mercury toxicity when ingested.

Industrial discharge into rivers and streams has been a major source of mercury pollution. The major dietary contribution comes from seafood. There is accumulation of potentially toxic

Table 6: Chelating Agents in Heavy Metal Poisoning

Chelating Agent	Dose	Precautions/Side Effects
Dimercaprol (BAL, British anti-lewisite)	300 to 450 mg/m²/d in 6 divided doses for 3 to 5 days deep intramuscularly	First dose precedes $CaNa_2EDTA$ by 4 hours Do not administer iron concurrently May produce hypertension, tachycardia, a constricting feeling in the chest, burning sensation in throat, lacrimation, urticaria, haemolysis (in G-6PD deficient patients)
$CaNa_2EDTA$ (edetate)	1000 to 1500 mg/m²/d for 5 days intravenously as infusion	Monitor renal functions Ensure adequate urine flow May produce fever, myalgia, tremors, headache, hypotension, vomiting, mild increase in liver enzymes, hypercalcaemia
DMSA (succimer)	10 mg/kg every 8 hourly for 5 days, then 10 mg/kg every 12 hourly orally	Monitor liver functions, blood counts May produce vomiting, diarrhoea, metallic taste, elevated liver enzymes, drowsiness, neuropathy, skin rash, nasal congestion, cardiac arrhythmia
DMPS (dimercapto-1-propane sulphonate)	5 mg/kg every 4 to 6 hourly orally or intravenously	Can be administered orally as well as parenterally
D-penicillamine	25 to 40 mg/d orally in 2 to 4 divided doses (maximum 1 g/day) orally	To be given empty stomach Monitor total leucocyte counts, platelets, haemoglobin, liver and renal functions Contraindicated in patients with penicillin allergy May produce rashes, arthralgia, lymphadenopathy, urticaria, vomiting, diarrhoea, bone marrow depression, nephrotic syndrome, neuropathy

quantities of mercury in freshwater fish in some lakes with acid water. Acidification increases bacterial formation of methylmercury, which then enters the food chain. *Minamata disease* was the first outbreak of methylmercury poisoning caused by consumption of methylmercury-containing seafood from the Minamata Bay in Japan in 1953. Later, another mass methylmercury poisoning was reported from Iraq where it was caused by contaminated bread.

Mechanism of Toxicity

After the inhalation of elemental mercury, approximately 80% is absorbed from the lungs and can cross the blood-brain barrier. The absorbed mercury is also rapidly oxidised to inorganic mercury in the red cells and tissues, which does not cross the blood-brain barrier effectively. After oral ingestion, elemental mercury is essentially unabsorbed. Inorganic mercury and phenylmercury are absorbed 7% to 15% after oral ingestion. These mercury compounds cross the blood-brain barrier poorly. Methylmercury is readily absorbed in the gastrointestinal tract. Mercurials bind to sulfhydryl groups present on the cell membranes and enzymes and cause their toxicities. Mercuric ions also accumulate in the kidneys, causing acute renal failure due to the necrosis of the proximal tubular epithelium, usually within 24 hours.

Clinical Features

Toxicity of mercurials depends on the form of mercury and on whether the exposure is acute or chronic.

Acute elemental mercury poisoning

Acute inhalation of elemental mercury results initially in pulmonary toxicity causing cough, haemoptysis, tachycardia, pulmonary oedema, cyanosis and death. Gastrointestinal features include vomiting, diarrhoea, metallic taste, dysphagia and salivation. If the patient survives, headache, blurred vision and encephalopathy can occur. Some patients develop cardiac arrhythmias, tremors, renal dysfunction and gingivostomatitis. Survivors of acute inhalation may develop interstitial lung fibrosis.

Oral ingestion of elemental mercury is associated with low risk of toxicity due to its limited absorption. Features of mercury toxicity may develop if there is inordinate delay of mercury passage through the gastrointestinal tract. In addition, mercury lodging in the appendix can cause appendicitis or a ruptured appendix.

Systemic features of mercury poisoning are usually absent after parenteral administration. Local features after parenteral administration include abscess formation with discharge of mercury granules, thrombophlebitis and granuloma formation. Embolisation of mercury may result in the presence of multiple, tiny spherules of mercury in various organs, including lungs, which are visible on a plain chest radiograph. Occasionally, intravenous injection of elemental mercury can cause severe pneumonitis and embolisation of the pulmonary vasculature, which can subsequently lead to hypoxia.

Acute inorganic mercury poisoning

Acute exposure to inorganic mercury salts results initially in gastrointestinal toxicity manifesting as abdominal pain, nausea, vomiting and in severe cases, bloody diarrhoea. This may result in vascular collapse. In high doses, renal necrosis and acute renal failure may occur and this is related to both hypovolaemia and direct renal toxicity.

Acute organic mercury poisoning

Acute exposure to phenylmercury and related organic mercury compounds other than methylmercury causes toxicity similar to that of inorganic mercury poisoning. Acute exposure to methylmercury causes similar effects that occur after its chronic exposure, but the onset of symptoms may be as early as 15 days after its ingestion.

Chronic mercury poisoning

Chronic exposure to elemental mercury vapour, inorganic mercury and phenylmercury produce similar toxic features. These include dermatitis, loosening of teeth, gingivitis, salivation, stomatitis, intention tremor and a neuropsychiatric syndrome called *'erethism'*. The features of erethism include loss of appetite, insomnia, emotional lability, loss of self-control and memory loss. Another syndrome, *'acrodynia'* or *'pink disease'* is characterised by painful, erythematous extremities, sweating, photophobia, tachycardia, hypertension, insomnia and irritability. It is probably a hypersensitivity reaction which occurs only in children and does not occur in newborns or adults. Renal dysfunction, ranging from proteinuria to immune-complex-mediated nephritis especially membranous nephropathy may occur.

Chronic methylmercury poisoning

Chronic exposure to methylmercury causes neurotoxicity with onset one to two months after initial exposure. Clinical features include cerebellar ataxia, dysarthria, constriction of visual field, hearing impairment, sensory disturbances in the distal parts of the extremities, and emotional and cognitive defects. Foetal exposure to methylmercury may cause cerebral palsy, microcephaly, mental retardation and developmental delay.

Dental amalgams

Dental amalgam, used to restore carious lesions in teeth, is approximately 50% metallic mercury. Small amounts of mercury vapour liberated by chewing may be inhaled and may result in measurable levels of mercury in the body. However, at present, there is no evidence that exposure to mercury from dental amalgams is associated with adverse psychosocial outcomes or other clinical features of chronic mercury poisoning.

Mercury in vaccines

Thiomersal, which contains approximately 50% ethylmercury, has been widely used as a preservative in multiuse vials of vaccines. In the United States, it has been removed from most childhood vaccines by 2001 as a precautionary measure. At present, there is no data to support that thiomersal may account for adverse neurodevelopmental outcomes in children.

Diagnosis

Diagnosis of mercury poisoning is aided by the determination of mercury levels in whole blood, 24-hour urine samples and hairs. For elemental mercury and mercury salts, whole blood mercury levels reflect only very recent exposure while urinary mercury is a better marker for chronic exposure. In contrast, since methylmercury (an organomercurial compound) is mainly excreted in bile, urinary level is a poor measure of exposure.

Blood mercury levels are the best indicator of acute exposure to methylmercury, while hairs may be the best specimen for the evaluation of chronic exposure. Normal levels of mercury in whole blood and urine are below 10 µg/L and 50 µg/L, respectively.

Abdominal radiographs can be used to document the presence of ingested mercury and to evaluate the potential benefit of gastric lavage. If the respiratory tract is involved, a chest radiograph may be helpful.

Treatment

Acute mercury poisoning is best managed by discontinuing the exposure, providing supportive care and removal of metal from the body. Patients with pneumonitis from acute elemental mercury inhalation require oxygen, close monitoring of respiratory status and if required, assisted ventilation. Although ingestion of elemental mercury is often nontoxic, some patients may require surgical removal of metal that is entrapped in the intestines or appendix. In case of subcutaneous injection of mercury, surgical removal of mercury and surrounding granulated tissue is important. Radiographs and blood, urine and hair assays for mercury are aids for instituting treatment with chelators.

Ingestion of inorganic mercury requires supportive treatment with aggressive fluid replacement and if required, haemodialysis. Patients should also be started on chelation therapy. Gastric lavage has been recommended for acute organic salt ingestions, especially if mercury is visualised on abdominal radiographs. Lavage may be done with protein-containing solutions, such as milk or egg white, as mercury may be bound to the administered sulfhydryl-containing proteins.

Whenever mercury poisoning is suspected in critically ill patients, chelation therapy should be started regardless of the suspected form of mercury; however, chelation may be ineffective at reversing toxicity from chronic organic and chronic elemental mercury exposure. Dimercaprol has been extensively used for inorganic mercury poisoning. However, it is contraindicated in methylmercury poisoning.

The DMSA and 2,3-dimercaptopropane-1-sulphonate (DMPS) are useful for both inorganic and elemental mercury poisoning. The DMSA is administered in a dose of 30 mg/kg per day. The duration of treatment is adapted to the evolution of clinical manifestations and urinary mercury levels. D-penicillamine is also useful in mercury poisoning although its efficacy is only about 30% of that with DMSA. It is administered in a dose of 250 mg 6 hourly along with pyridoxine (40 mg/day). This is continued till the urinary mercury levels fall below 500 µg/L after which the dose is reduced to 250 mg thrice daily. The DMPS has also been used with N-acetylcysteine (NAC) and haemodialysis as a part of a successful regimen for acute methylmercury poisoning. The NAC has also been used as a single agent in the treatment of acute elemental mercury poisoning. Oral DMPS may also be useful in mercury inhalational poisoning.

COPPER

Copper is an ingredient of several vital enzymes. It exits as elemental copper or as salts. Elemental copper is not toxic, but many of its salts are poisonous. Common salts include cupric acetoarsenite (Paris or Vienna green), cupric arsenite (Scheele green), cupric oxide, and copper or cupric sulphate (*'neela thotha'*). Most of the salts of copper are greenish in colour except for copper sulphate, which is blue in colour. Copper compounds are used as insecticides and fungicides and also as pigments. Acute or chronic copper poisoning can occur when copper ions are leached from copper pipes. Storage of acidic substances, such as orange juice in copper containers, may cause poisoning. Copper sulphate poisoning, one of the most common poisonings in 1960s and 70s in India, has reduced significantly over the past four decades.

Mechanism of Toxicity

In an acute intoxication, a high fraction of copper is bound to serum albumin and is biologically active. It is actively involved in oxidation-reduction reactions in the body, which is responsible for its toxicity. It inhibits several enzymes including mitochondrial electron transport chain and also disrupts lipid membranes. It also inhibits sulfhydryl groups on enzymes, including glucose-6-phosphate dehydrogenase and glutathione reductase, which may be responsible for haemolysis.

Clinical Features

Acute poisoning

The average fatal dose of copper sulphate is 10 to 20 g. Initial features of acute poisoning include myalgia, retrosternal pain, abdominal pain, vomiting (greenish or bluish) and diarrhoea. Gastric perforation or haemorrhage can occur due to ulceration. Acute intravascular haemolysis occurs within 24 hours and can lead to anaemia, jaundice and renal failure. Jaundice may also occur due to liver injury. Some patients may develop methaemoglobinaemia due to oxidation of haeme and this may precede haemolysis. The central nervous system effects include agitation, convulsions and coma and are usually related to hepatic failure. Hypotension and cardiovascular collapse occur due to fluid loss from gastrointestinal tract; direct effects of copper on heart and vascular tree may also contribute to shock.

Chronic poisoning

Chronic exogenous copper poisoning is uncommon. Chronic inhalation of copper sulphate spray used as an insecticide can produce interstitial lung disease, the latter having histiocytic granulomas containing copper on biopsy. In children, consumption of copper-containing supplements over long periods may produce liver damage and cirrhosis. Other features include malaise, weakness, headache, dizziness, tightness in the chest, and leg and back pain.

Diagnosis

Following acute copper poisoning, liver function tests and haemogram may reveal evidence of haemolysis and liver damage. Blood copper level more than 1.5 mg/dL indicates serious copper toxicity. Elevated copper levels are also seen in patients with inflammatory conditions. Urinary copper levels are also elevated (normal urinary copper value < 25 µg/day).

Treatment

Aggressive supportive care is the mainstay of management of patients with acute copper poisoning. The fluid and electrolyte balance must be ensured. Gastrointestinal decontamination is usually not required as the patient vomits within minutes of ingesting a copper salt. When the patient presents early after ingestion, administration of milk may help, as albumin present

in milk combines with copper. Haemodialysis is of little use in enhancing excretion of copper. Since methaemoglobin produced by copper is released into plasma due to intravascular haemolysis, methylene blue is not useful for its treatment.

Chelation therapy is indicated when haematological or hepatic manifestations are present even though the efficacy of chelators is not well studied. Most commonly recommended chelator initially is BAL as the patient has vomiting, and therefore, oral D-penicillamine cannot be given. When tolerated, D-penicillamine should be started. The DMSA may be used in patients with mild symptoms. Use of DMPS may worsen haemolysis and therefore, is not recommended in copper poisoning.

THALLIUM

Thallium metal is nontoxic, but its salts are highly toxic. Thallium salts are tasteless, colourless and odourless. Thallium sulphate and nitrate were used as rodenticides. Some thallium salts are occasionally used as cockroach poison. It is still used in some homeopathic medicines. Thallium is widely used in industry. It is used in imitation jewellery, which sparkles rather like diamonds. It is also used as an alloy, a catalyst, and for making low-temperature thermometers and semiconductors. Thallium isotopes are used in nuclear medicine.

Mechanism of Toxicity

Thallium salts can be absorbed from the skin as well as by inhalation and ingestion. After absorption, thallium distributes throughout the vascular space in the first few hours. After several hours to days, it enters the nervous system and other tissues of the body. Thallium associates with the Na^+/K^+ ATPase channel with 10 times the affinity of potassium. Once intracellular stores of thallium accumulate, thallium interferes with the function of a number of enzymes by binding sulfhydryl groups and ultimately inhibiting cellular respiration, disrupting calcium homeostasis, and interacting with riboflavin and riboflavin-derived cofactors. Secondary riboflavin deficiency can then result in dermatitis, alopaecia, Mees' lines and neuropathy. The fatal dose of thallium is estimated to be 10 to 15 mg/kg.

Clinical Features

The initial clinical features of thallium intoxication are nonspecific and usually develop after several hours of exposure. The gastrointestinal symptoms are usually not severe and include nausea, vomiting, abdominal pain and diarrhoea or constipation. Within 2 to 5 days, the patient may develop paraesthesia, burning pain in feet and hands, motor weakness, respiratory depression, nystagmus, optic atrophy, cranial nerve palsies, delirium, convulsions and coma. The picture may resemble Guillain-Barré syndrome superficially, but sensory neuropathy and preservation of reflexes exclude this syndrome. Tachycardia and hypertension frequently develop during the first or second week of intoxication. Within 2 to 3 weeks, skin lesions (acne, palmar erythema, dry skin and occasionally a 'butterfly' rash on the face) and alopaecia develop. The hair is lost in large tufts and within three weeks, the whole of head is bare. Mees' lines on the nails may be seen in 2 to 4 weeks. Cardiac arrhythmias may occur up to 2 months after exposure.

Diagnosis

Abdominal radiographs may demonstrate radio-opaque material in the gut when patient presents early. Microscopic examination of hair root shows deep black pigmentation in more than 95% cases. The definitive diagnosis can be made by blood and urine thallium levels. Normal urine thallium levels are less than 5 µg/L.

Treatment

The initial treatment is supportive and includes gastric decontamination if the patient presents shortly after ingestion. Activated charcoal is useful in adsorbing substantial amount of thallium salts.

Administration of potassium increases the excretion of thallium in the urine by 2 to 3 times. However, it can potentially increase neurologic toxicity due to mobilisation of thallium from its stores, and is therefore, not recommended. Administration of B-complex vitamin may be useful. Haemodialysis and haemoperfusion have been used with some success.

Traditional chelators are of little use in thallium poisoning. Prussian blue (potassium ferric hexacyanoferrate) can be used as a chelator. Oral Prussian blue binds with thallium in the gut and also interferes with enterohepatic circulation. It reduces half-life of thallium by 50% in animal models. The dose is 250 mg/kg/day in 2 to 4 divided doses.

CONCLUSION

Heavy metal poisonings with lead, mercury, arsenic, copper and thallium are infrequently encountered; however, early recognition of these poisonings is required for efficacious treatment and a favourable outcome. A thorough history (including occupational) and physical examination are essential for the accurate diagnosis.

26.14 Miscellaneous Poisoning

Subhash Varma, Vikas Suri

CARBON MONOXIDE POISONING

Carbon monoxide (CO) is a colourless, tasteless and odourless (lavender odour at extremely high concentrations) gas with a density of 0.97 that of air.

Sources of Carbon Monoxide

Sources of CO from combustion include fuel, engine exhaust and gas/coal-heater emissions, smoke from accidental fires and fumes from cupolas of steel foundries, pulp paper mills and formaldehyde-producing plants. Indoor burning of charcoal or animal dung produces a disproportionate level of accidental CO intoxication. CO poisoning can also result from inhaling methylene chloride or volatile liquids found in degreasers, solvents and paint removers.

Mechanism of CO Toxicity

Since CO has 200 to 250 times greater affinity for haemoglobin than oxygen, it displaces oxygen from oxyhaemoglobin (HbO_2) and converts it into carboxyhaemoglobin (COHb) causing decreased oxygen delivery to tissues. It also shifts the oxygen dissociation curve to left and reduces oxygen availability to the tissues further. It also acts as cellular poison as it competes with oxygen for other haemoproteins such as myoglobin, peroxidase, catalase and cytochromes. High-oxygen-extracting organs such as the brain and the heart easily become dysfunctional from CO intoxication.

Activation of inflammatory processes and resultant lipid peroxidation play a role in the development of neurological damage. They contribute to the development of systemic inflammatory response syndrome (SIRS) and delayed neurological sequelae (DNS).

Clinical Features

Signs and the symptoms of CO poisoning are related to effects of hypoxaemia predominantly on the heart and brain. Concentrations of CO, duration of exposure as well as level of activity of the victim at the time of exposure have a bearing on clinical picture.

Acute Poisoning

Headache is the earliest symptom of mild to moderate toxicity. Subsequently dizziness, nausea, dyspnoea and loss of muscle control develop. Severe CO intoxicated patients have cherry pink colour of the skin, nails and mucosa. Ophthalmoscopy may show retinal discolouration with bright red retinal veins, flame-shaped retinal haemorrhages or papilloedema. In severe cases hypotension, bradycardia, bradypnoea and noncardiogenic pulmonary oedema may develop.

Neurologic symptoms and signs include fatigue, malaise or flu-like symptoms, nausea, vomiting, dizziness, weakness, lethargy, difficulty in thinking, concentration and memory, emotional lability, paraesthesia, somnolence, stroke, coma, seizure, and respiratory arrest.

Cardiovascular symptoms and signs include chest pain from myocardial ischaemia, palpitations from arrhythmia, mildly to severely mottled skin from diminished circulation, poor capillary refill, hypotension, and cardiac arrest.

The symptoms and signs of CO toxicity are exacerbated by circumstances that increase neurologic and myocardial oxygen demand.

Subacute Poisoning

Secondary injury from ischaemia due to CO poisoning can manifest within a few days of exposure as peripheral neuropathy, skin lesions (bullae and purpuric spots), rhabdomyolysis, renal failure, circulatory shock, noncardiogenic pulmonary oedema, disseminated intravascular coagulation and multi-organ failure. Glycosuria and albuminuria are often present.

Delayed Neurologic Sequalae (DNS)

DNS can arise 3 to 240 days after apparent recovery in approximately 40% of patients with significant CO exposure. These include headache, weakness, dizziness, nausea, aphasia, apraxia, apathy, disorientation, hallucinations, rigidity, gait disturbances and faecal and urinary incontinence. DNS generally occurs within 20 days of CO poisoning but deficits may persist for a year or longer. DNS correlates poorly with COHb levels. However, loss of consciousness, advancing age and neurological signs during acute intoxication may increase the risk.

Chronic Exposure

Long-term, low level exposure may result in light-headedness, persistent headaches, confusion, memory loss, nausea, vomiting and depression that tend to get better on cessation of exposure. Long-term exposure to CO can promote the development of atherosclerosis and polycythaemia.

Diagnosis

Acute CO poisoning is suspected on a suggestive history but the diagnosis of chronic CO intoxication is extremely difficult. Standard pulse oximetry does not differentiate COHb from HbO_2 and is a poor indicator of CO exposure. Eight-wavelength pulse oximeters capable of measuring COHb and methaemoglobin are being developed but need further validation. COHb is estimated by spectrophotometry. It may be tested on bedside by adding 10 mL of distilled water and 1 mL of 5% sodium hydroxide (NaOH) to 1 mL of patient's blood. The solution turns straw yellow when COHb concentration is < 20% and stays pink when it is > 20%. Non-invasive pulse co-oximeters capable of photo-spectroscopic measurements of COHb are in development stage.

On-site CO-oximetry determination of COHb levels correlate reasonably well with the signs and symptoms of CO injury.

However, the predictive values of COHb levels falls considerably by the time, the patient gets to the emergency department after breathing air as well as prehospital oxygen administration but a rough correlation can be made with various clinical manifestations (Table 1).

Table 1: Symptoms of Acute CO Poisoning Based on Blood Carboxyhaemoglobin Levels

Carboxyhaemoglobin Level	Clinical Features
<10%	Very few, mainly headache
10% to 20%	Dyspnoea on exertion, lethargy, nausea, chest pain, tightness around forehead
20% to 30%	Headache, irritability, fatigue, nausea, vomiting, disturbed judgement, vision and vertigo
40% to 50%	Severe headache, confusion and collapse
50% to 60%	Same as above + syncope, Cheyne-stroke breathing, fits
60% to 70%	Coma, seizures, weak thready pulse and slow breathing, respiratory failures and death
80%	Rapidly fatal

Other investigations include complete blood counts (CBC), renal functions, metabolic profile, urinalysis, creatine kinase, ECG, cardiac enzymes and coagulation profile. Imaging studies like chest radiography, CT and MRI scans may be done to assess organ damage.

Treatment

Prehospital care

The ABCs (airway, breathing, and circulation) of resuscitation apply to the seriously ill or injured victims with presumed CO intoxication. The patient must be removed promptly from the source of CO exposure.

Hospital care

Patients with only mild symptoms (nausea, headache, weakness, or flu-like malaise) should receive 100% normobaric oxygen (NBO) for a period of about 4 hours with periodic re-assessment. The ability of oxygen treatment to eliminate CO from the body has often been estimated using the half-life of COHb with different treatment regimens which is 3 to 4 hours while breathing room air, 60 minutes with 100% NBO and 15 to 23 minutes with 100% hyperbaric oxygen (HBO) at 2.5 to 2.8 atmospheric pressure. A patient with mild symptoms will require oxygen for 4 to 6 hours or until COHb level is <5%. HBO treatment has been used in patients with major symptoms (any history of loss of consciousness, profound dip in blood pressure, amnesia, or myocardial ischaemia) with dramatic improvement. However, its superiority over NBO with regard to short- and long-term outcomes is controversial since HBO use is associated with barotrauma, ear pain and oxygen toxicity.

OZONE (O_3) POISONING

Ozone (O_3) is widely used by cleaning services for use in indoor building environments to deodorise, disinfect, 'kill' mould and for 'general health' and generating equipment companies. It is formed as an atmospheric pollutant by the action of sunlight on air having hydrocarbons and nitrogen oxide. Ozone toxicity is due to its oxidative potential and most commonly reacts with amino acids, peptides and other proteins as well as unsaturated fatty acids in the fluid layer of lung lining and epithelial cell membrane making lungs most commonly affected organ. The ozonisation of the fatty acids leads to the release of pro-inflammatory mediators in the lung resulting in inflammatory damage.

Clinical Features

Ozone at a concentration of 0.25 to 0.75 ppm (parts per million) causes shallow rapid breathing, cough, tightness in the chest and dryness of throat. It also increases the sensitivity of the lungs to allergens, histamine and acetylcholine.

Prevention

Ozone toxicity can be prevented by vitamin C, alpha tocopherol and sulfhydryl compounds in laboratory animals. Glutathione depletion affects the cellular sensitivity towards ozone. Alpha tocopherol has significant scavenging action.

CYANIDE POISONING

Cyanide is a potent cellular toxin and one of the most rapidly acting poisons. Common sources of exposure include: (a) occupational settings: electroplating plants, photographic development, plastic production, (b) inadvertent, suicidal, or homicidal ingestions, (c) patients on infusions of sodium nitroprusside, and (d) inhalation of smoke from burning plastics in closed-space fires. The natural source of cyanide includes bitter almond, apricot, peach, plums, apple, raw papaya, pear seeds and *Sorghum* grass (African cereal).

Pathophysiology

The avidity with which cyanide binds to metal-containing enzymes accounts for its serious cellular toxicity. By binding to iron of mitochondrial cytochrome C, it inhibits cellular respiration that results in anaerobic metabolism with increased lactic acid production and cell death.

Clinical Features

The time course and severity of the clinical effects of cyanide are a function of the nature of the cyanide-containing compound, the route of exposure, and the concentration of cyanide to which the patient is exposed. When inhaled, rapidly progressive and potentially fatal symptoms are evident within seconds. Concentration of < 50 ppm causes restlessness, anxiety, palpitations, dyspnoea, and headache. Higher levels of hydrogen cyanide (HCN) gas cause severe dyspnoea, loss of consciousness, seizures and cardiac arrhythmias, and cardiovascular collapse. Still higher levels are fatal and median lethal dose (LD50) for humans is estimated to be 200 ppm for a 30-minute exposure and 600 to 700 ppm for a 5-minute exposure.

On examination, patient may be anxious with a breath smelling like bitter almonds or garlic. The skin may appear cherry red and those with smoke inhalation may have soot over skin, mouth and nose. Other manifestations include tachycardia, hypotension and shock, irregular acidotic breathing, cyanosis, alteration in sensorium, confusion, ataxia, tonic and clonic seizures, paralysis and coma. Fundoscopy shows bright red retinal arteries and veins with dilated reactive pupils.

Investigations

Direct measurement of blood cyanide levels is not generally available. Plasma lactate level > 8 mmol/L is highly suggestive. Severe metabolic acidosis is a consistent accompaniment and its absence virtually excludes the diagnosis of cyanide toxicity. COHb levels are undertaken to rule out associated CO exposure.

Decreased cellular extraction of oxygen is reflected by an increased oxygenation of venous blood and decreased normal arterio-venous oxygen [(a-v) O_2] difference. Electrolytes are measured for anionic gap. Other causes of anion gap and metabolic acidosis need to be excluded. Imaging is not needed for acute poisoning but MRI may be required in case late neurological effects appear.

Treatment

Though severely poisoned patients may survive with supportive care (100% oxygen, intravenous fluids), use of antidote in massive exposure improves survival. Gastric decontamination should never take priority over resuscitation of the symptomatic patient. Crystalloids, vasopressors and sodium bicarbonate are used as per clinical indications.

Antidote therapy

Nitrites: Nitrites result in production of methaemoglobin which binds avidly to cyanide, frees cytochrome and restores aerobic cellular respiration. Ten millilitres of 3% solution of sodium nitrite is administered by slow intravenous infusion. It should be avoided in victims of smoke inhalation unless the COHb levels are <10%. Sodium nitrite is followed by administration of sodium thiosulphate (adult dose 50 ml of 25% of solution - 12.5 gm) at 5 ml per minute over 10 minutes. Sodium thiosulphate enhances the activity of the enzyme rhodanese. Twenty-five millilitres of 25% solution is repeated after 30 minutes. It is desirable to keep methaemoglobin levels below 30%. Significant side-effects include hypotension and excessive methaemoglobinaemia. Cyanide antidote kit (CAK) contains amyl nitrite pearls, sodium nitrite and sodium thiosulphate.

Hydroxocobalamin: It directly chelates cyanide and restores cytochrome oxidase aerobic respiration. Hydroxocobalamin (adult dose 50 mg/kg or 4 gm intravenous over 30 minutes) is used in combination with sodium thiosulphate.

METHAEMOGLOBINAEMIA

Methaemoglobinaemia results from conversion of ferrous ion on haem to ferric ions. Methaemoglobin has high affinity to oxygen and impairs oxygen delivery to the tissues. It may be congenital (deficiency of NADH methaemoglobin reductase) or acquired secondary to several drugs or chemicals that cause oxidative stress (**Table 2**). Concomitant oxidation of haemoglobin protein may cause its precipitation and a haemolytic anaemia.

Clinical Features

Clinical features are dependent upon not only the level of methaemoglobin (**Table 3**) but also on its rate of formation and associated toxicity of the responsible toxin.

Laboratory Diagnosis

Blood appears chocolate brown in colour. For a bed-side test when one to two drops of patient's blood are put on white filter paper a chocolate brown colour, which does not change with time, is observed. PaO_2 as well as calculated saturation is relatively the normal but measured arterial oxygen saturation (SaO_2) is reduced. This oxygen saturation gap, i.e. the difference between the calculated and the measured oxygen saturation, is >5% in normal circumstances.

Estimation of methaemoglobin in the blood is needed to confirm the diagnosis. Normal methaemoglobin levels are <1%. This widely available test requires only a venous specimen, although arterial blood may be used if arterial puncture is indicated for another reason.

Table 2: Chemicals Inducing Methaemoglobinaemia

Amyl nitrite	Naphthalene
Aminophenol	Nitrobenzene
Aniline dye and its derivatives	Nitroglycerine
Chlorates	Nitroprusside
Chloroquine and primaquine	Oxides of nitrogen
Copper sulphate	Paraquat
Lidocaine, benzocaine	Phenacetin
Local anaesthetic agent	Phenazopyridine
Metoclopramide	Sulphonamides, Dapsone

Table 3: Clinical Features of Methaemoglobinaemia

Methaemoglobin Concentration	Clinical Features
0% to 3%	Asymptomatic
3% to 15%	Usually no features
15% to 20%	Cyanosis with grey-brown hue, unresponsive to oxygen
20% to 50%	Dyspnoea, headache fatigue, syncope, weakness, dizziness, tachycardia
50% to 70%	Tachypnoea, hypoxia, metabolic acidosis, seizure, arrhythmia, central nervous system (CNS) depression, bradycardia
>70%	Haemolytic anaemia, renal failure, coma and death

Treatment

The toxin if recently ingested should be removed by gastro-intestinal decontamination. Mild methaemoglobinaemia with levels ≤20% can be treated with oxygen supplementation. Antidotal therapy with methylene blue is reserved for patients with severe methaemoglobinaemia. Methylene blue indirectly accelerates the enzymatic reduction of methaemoglobin by NADPH-methaemoglobin reductase. It is administered intravenously in a dose of 1 to 2 mg/kg body weight as a 1% solution slowly over 5 minutes. If significant improvement does not occur in an hour, it can be repeated. It results in bluish discolouration of skin and urine that may make clinical assessment of true cyanosis difficult. Side effects include precordial chest pain, dyspnoea, restlessness, apprehension and tremor. Highly unstable patients may additionally benefit from exchange transfusion through immediate enhancement of oxygen delivery. Exchange transfusion may also be used in G6PD deficiency where methylene blue is contraindicated. Inappropriate response to methylene blue may be seen following dapsone intake and sulphaemoglobinaemia. Vitamin C, a slow acting drug for methaemoglobinaemia, may be tried if methylene blue is not available. Dialysis may be useful.

HYDROGEN SULPHIDE

Hydrogen sulphide is a colourless irritant gas that is heavier than air with an odour of rotten eggs. It is formed in sewers and cesspools. It causes cellular asphyxia through the inhibition of the mitochondrial cytochrome a3.

When inhaled in pure form, it is almost immediately fatal, causing coma and respiratory failure. It causes irritation of eyes, nose, throat and respiratory passages at low concentration whereas higher concentrations would cause dizziness, headache, vomiting, abdominal pain, cyanosis, dilated pupils, laboured breathing, irregular pulse, seizures, delirium, stupor, coma and death. Pulmonary oedema and adult respiratory distress syndrome may occur. Pharyngeal and conjunctival erythema and corneal abrasions are observed on clinical examination.

Treatment

The victim must be removed from the source of exposure and resuscitated at site. Hospital management consists of control of hypoxia, seizures, pulmonary oedema and acidosis. Hyperbaric oxygen therapy has been found to be useful. If not available, patients should receive 100% oxygen. Inducing methaemoglobinaemia using amyl nitrite and sodium nitrite has been found to be useful as methaemoglobin has higher affinity to hydrogen sulphide than to cytochrome oxidase. Sodium thiosulphate use is not beneficial.

COPPER SULPHATE

(CUPRIC SULPHATE, BLUE VITROL, BLUE STONE, *NILA THOTHA*)

Copper sulphate, a blue, crystalline irritant, is used chiefly in agriculture as a pesticide, herbicide or fungicide. It is also used in leather industry and was in the past used as a precipitator in heavy metal poisoning as well as in the treatment of gastric and topical exposure to phosphorous. It has a nauseous and metallic taste. Solutions are acid to litmus. Fatal dose is 15 to 30 g.

Clinical Features

Copper sulphate is absorbed from the skin as well as gastrointestinal tract. Skin exposure results in burning pain and itching. Eye contact causes redness and corneal injury. Oral ingestion results in a metallic taste, salivation, thirst, nausea, abdominal pain and recurrent vomiting within 15 to 30 minutes. The vomitus is blue or green that turns deep blue on addition of ammonium hydroxide. Painful diarrhoea may occur. Systemic copper toxicity affects first erythrocytes and then the liver and kidneys. Intravascular hemolysis appears 12 to 24 hours following its ingestion either due to direct red cell membrane damage or secondary to the inactivation of enzymes (including glutathione reductase) that protect against oxidative stress. It is followed by jaundice, oliguria and renal failure. Cramps in the legs, spasm or convulsion can occur. Large dose produces frontal headache and circulatory collapse. Severe neurological symptoms include paralysis of the limbs, drowsiness and coma. Fatalities are known in severe poisoning.

Treatment

Treatment is mainly symptomatic and supportive. Ovalbumin or 1% potassium ferrocyanide should be used for gastric lavage. Patients with renal failure need dialysis.

HOUSEHOLD POISONS

Kerosene Oil

Kerosene oil, a petroleum product, is a mixture of hydrocarbons contaminated with organic sulphur. Petrol, gasoline, vaseline and paraffin are other related hydrocarbons. Besides household cooking and burning, kerosene is used as paint thinner. Lethal dose of kerosene oil is 30 to 100 mL.

Clinical features

Kerosene is toxic both through inhalational and oral routes. Inhalation results in dizziness, nausea, vomiting, burning sensation in chest, dry cough, headache and ataxia. Severe poisoning produces pulmonary oedema, haemoptysis, mental confusion, hallucinations, stupor, cyanosis, convulsion and coma. Death is mainly due to ventricular fibrillation and respiratory failure. Ingestion of kerosene oil produces burning pain in the mouth, throat, dry irritating cough, nausea, vomiting, colicky abdominal pain and diarrhoea. Large quantity of oil can produce neurological dysfunction similar to the one described for inhalational toxicity. The pupils are initially constricted and later dilated. Aspiration of as little as 0.2 mL of kerosene oil can produce chemical pneumonia and pulmonary oedema. The breath, vomitus and urine gives off the peculiar smell of kerosene. The chest radiograph may reveal perihilar densities, basal pneumonia, and atelectasis.

Treatment

In case of inhalational toxicity, remove the victim to open air, ensure patent airway, keep the body warm and on hospitalisation administer oxygen. Follwing ingestion, induction of vomiting or gastric lavage is contraindicated due to increased risk of aspiration. Activated charcoal is not useful. Antibiotic and steroids are not indicated. Victims with severe respiratory symptoms and abnormal radiography should be observed for complications and managed appropriately for at least 2 to 3 days.

Hair Dye

Hair dyes are classified as oxidative dyes (permanent), direct dyes (semi-permanent or temporary), metal salts and natural salts. Most of the modern commercially available oxidative dyes consist of two components that are mixed prior to use and generate the dye on/in the hair by oxidative chemical reaction. They contain several ingredients which includes primary intermediates (para-phenylenediamine [PPD], para-toluenediamine [PTD], substituted para-diamines, ortho- or para-aminophenols), couplers or modifiers (m-phenylene-diamines, m-aminophenols, resorcinol), oxidants and alkalinising agents. PPD is an aromatic amine $C_6N_4(NH_2)_2$ in which at least one hydrogen of the cycle has been replaced by an amine substitute. For dyeing purposes, PPD is added with hydrogen peroxide resulting in the formation of Bandrowski's base, which is highly allergic and toxic. The principal adverse effect of high oral doses of PPD in man and higher mammals is angioneurotic oedema leading to acute respiratory distress. It may cause acute renal failure secondary to rhabdomyolysis, hypovolaemia, intravascular haemolysis or direct toxic effects of PPD or its metabolites on the kidneys. Other less commonly reported features of PPD poisoning are liver failure, drowsiness, altered sensorium and convulsions, gastrointestinal symptoms, exophthalmos and chronic renal failure.

Treatment of systemic PPD poisoning is mainly supportive as there is no specific antidote. Early clinical diagnosis and therapeutic interventions in the form of tracheostomy, intravenous fluids and haemodialysis leads to full recovery.

Household and Toilet Cleaners

Cleaners that are usually toxic when ingested include dishwasher, toilet bowl, and oven cleaners. They can pose a significant risk, especially in children and elderly, but majority of the affected individuals have minimal or no side-effects.

Detergents

These are products that contain anionic surfactants and detergent builders, such as sodium phosphates, sodium carbonate and sodium aluminosilicates, which are highly alkaline. Detergents fall into three main categories—nonionic, anionic, and cationic. Nonionic and anionic detergents are of low toxicity. Cationic detergents, such as benzalkonium chloride and cetrimide, are less frequently encountered in domestic cleaners and produce corrosive effects if a concentrated solution is consumed. The route of exposure is almost always oral ingestion but inhalational, ocular and dermal exposures and even intravenous route have been reported. Corrosive injury to the gastrointestinal, respiratory and corneal mucosa (depending on route of exposure), cardiac dysfunction, acute renal failure with rhabdomyolysis, ARDS (early and late onset), haemolysis, frequent ventricular tachycardia and coagulation abnormalities have been reported secondary to exposure to household detergents. There is no standardized treatment protocol for detergent poisoning. Endotracheal intubation and supportive ventilation are required frequently. Syrup of ipecac is not advised due to the risk of aspiration and further caustic injury to the oesophagus.

Toilet Rim Block

Disinfectant used in flush toilets is made from anionic surfactants. It may be of two types, in cistern or rim blocks. The composition can vary, but they contain borax, troclosene sodium, sodium percarbonate, sodium carbonate (washing soda). Systemic toxicity is low but local corrosive action predominates if ingested.

Bleaches

These household solutions contain approximately 3% to 10% sodium hypochlorite or less commonly 3% hydrogen peroxide. These are extremely unpalatable and unlikely to cause serious damage. Symptoms are same as that of caustic ingestion but respiratory symptoms may result when bleach is mixed with ammonia (producing chloramine gas) or with toilet cleaners, (forming chlorine gas).

Treatment

Removing the patient from the source and minimising the period of contact between the corrosive and the tissue will prevent tissue damage. Irrigation with copious amount of water is paramount as prompt dilution reduces the exposure. Patients with respiratory distress may have significant oral, pharyngeal, and/or laryngotracheal injury necessitating emergency airway management. Prior to intubation, extent of airway injury should be assessed by fiberoptic endoscopy. Early endoscopy is indicated in patients with corrosive ingestion for prognostication and should be done as soon as the patient is haemodynamically stable. Before endoscopy, perforation should be ruled out. Endoscopy can also be used to place a naso-jejunal tube across the lesion so as to facilitate early initiation of enteral feeding.

Rodenticides/Insect Repellent

Rodenticides usually contain hydroxycoumarin anticoagulant. Second-generation superwarfarins and the indandione derivatives were introduced when rodent resistance to warfarin began to appear. Others contain bromethalin, cholecalciferol, alpha chloralose strychnine and zinc phosphide. Alphachloralose causes central nervous system (CNS) depression. Most one-time warfarin ingestions are insignificant accidental poisonings and do not cause any bleeding problems. Toxicity requires large amounts in a single exposure or a repetitive exposure over several days. Therapy is not necessary for ingestion of a single mouthful of warfarin. The superwarfarins have a longer biologic half-life; a single ingestion may result in marked anticoagulation effects for weeks to months. Acute intentional or repeated ingestions can cause severe bleeding. For potentially toxic ingestion, therapy consists of activated charcoal and a cathartic, with a baseline International normalisation ratio (INR) determination and repeated in 12 to 24 hours. If the INR is greater than twice the normal, vitamin K (phytonadione) administration is indicated.

Boric Acid
(Boracic Acid, Acidum Boricum, H_3BO_3)

Boric acid, an odourless white powder, is used as an antiseptic, effective agent against cockroach infestation as well as in leather industry and the production of glaze and enamel. The usual fatal dose of boric acid is 15 to 20 g for adults and 5 g for children.

Clinical features

The victim presents with anorexia, nausea, vomiting and epigastric pain. Skin involvement occurs within 1 to 3 days of ingestion. Skin turns erythematous with bullae and blisters initially over the hands that become generalised. Severe intoxication results in acute kidney injury and renal failure. Bloody diarrhoea with severe colicky abdominal pain and jaundice can occur. Other symptoms include malaise, lethargy, headache, restlessness, hyperpyrexia, muscle twitchings, tremors, seizures followed by coma and Cheyne-Stoke respiration. Chronic poisoning may lead to diffuse alopecia, raw tongue anorexia and renal damage.

Management

It includes gastric lavage and activated charcoal to remove the toxin, administration of intravenous crystalloids with alkaline solutions and glucose to ensure adequate urine output. Boric acid is dialyzable. Renal failure is managed like any other acute renal injury. Oxygen and artificial ventilatory support are required for respiratory failure.

Essential Oils

These are volatile mixtures of esters, alcohols and ketones. Some substances, e.g. camphor, an active ingredient of common OTC products such as Vicks Vapo Rub are very toxic. Mucosal irritation, vomiting, epigastric pain may be followed by

secondary hepatic and renal failure in severe toxicity. Clinical observation and supportive treatment is needed.

Nail Care/Nail Varnish Removers

These contain acetone or ethyl acetate. Irritation of mucous membranes, vomiting, CNS depression, ketosis, acidosis and hyperglycaemia are commonly observed. Presence of other solvents may lead to different complications like caustic injury (methanol/methacrylic acid), methaemoglobinaemia (nitroethane) and cyanide poisoning (acetonitrile). Hospital admission is needed in symptomatic individuals. Nitroethane and acetonitrile ingestions require referral to the emergency.

Naphthalene

It is a hydrocarbon contained in the middle oil distillation of coal tar. It is chiefly used in the manufacturing of certain azo dyes, moth repellent, wood preservative and deodorant. Ingestion of naphthalene produces nausea, vomiting, loose motions, headache, gait disturbances, drowsiness, muscle twitching, cyanosis and profuse perspiration. Severe toxicity produces jaundice, haemolytic anaemia in G6PD deficient individuals, albuminuria, haematuria and acute renal failure. CNS manifestations include encephalopathy, seizures, coma and death. There is no specific antidote; hence the treatment consists of gastric lavage, saline purgative, intravenous fluids, sodium bicarbonate, blood transfusion and diuretics as supportive therapy.

PHOSPHORUS

Of the two varieties, yellow or white is more toxic than the red phosphorus. White phosphorous on exposure to light slowly oxidises and emits white fumes of phosphorus trioxide that has garlic-like odour and is luminous in dark. Red phosphorus is tasteless, odourless, not luminous and nonpoisonous substance that is used in the manufacturing of safety matches.

Clinical Features

It acts rapidly when, for example, ends of lucifer matches are swallowed, through mistake or malice. The fatal dose of yellow phosphorus is 10 to 100 mg. Symptoms develop after a latent period of 1 to 6 hours. Large dose produces severe vomiting, retrosternal and epigastric burning associated with unquenchable thirst. The vomitus is luminous in the dark and may be associated with haematemesis. Large offensive smelling diarrhoea indicates severe toxicity. These symptoms are relieved temporarily after 24 to 48 hours. Subsequently, features of hepatic failure and renal failure may develop after 1 to 6 days. Liver injury is characterised by jaundice with severe pruritis that is associated with pain in stomach, vomiting with haematemesis and bleeding from various sites. Renal involvement leads to oliguria and renal failure. Urine is high coloured with albuminuria, bile pigments, casts and occasionally leucine, tyrosine and cystine crystals. Electrolyte disturbances, hypoglycaemia and hypoprothrombinaemia are often present. CNS symptoms in severe intoxication include severe frontal headache, hallucinations, restlessness, insomnia, tinnitus, tremors, deafness, drowsiness, convulsions and coma. Cardiac toxicity may lead to severe depression of cardiac function leading to circulatory failure and arrhythmia. Priapism, severe delirium and convulsions with peripheral circulatory failure precede death.

Chronic poisoning with yellow phosphorus produces necrosis of mandible, cachexia and anaemia.

Treatment

There is no specific antidote for phosphorus. The treatment is mainly supportive.

CHLORATES

Sodium potassium chlorates, used as weed killers, in matches and mouthwashes, are strong oxidising agents. These cause damage to the liver, kidneys and the circulating cells. Liver injury and disseminated intravascular coagulation are common features of intoxication. Death during early phase of intoxication is due to dineminated intravascular coagulation (DIC) or hypoxia caused by methaemoglobinaemia and haemolysis and renal failure in late stages. The treatment is mainly supportive. Sodium thiosulphate inactivates chlorates and hence, it can be used as lavage fluid. Use of vitamin C and methylene blue is ineffective in converting methaemoglobin into haemoglobin. Exchange transfusion, peritoneal dialysis and haemodialysis have been found to be effective in some cases.

HYDROGEN PEROXIDE

Hydrogen peroxide is available as 3% solution for use as an antiseptic. However, industrial grade solution is 35%. Ingestion of 3% solution is generally nontoxic as it is converted into water and oxygen in the stomach. Since the volume of oxygen liberated is 10 mL per millilitre of hydrogen peroxide solution, ingestion of large amount of dilute solution may produce gastric distension. If large amount of solution containing higher concentration (>10%) of hydrogen peroxide is ingested, the patient may develop coma, cyanosis, hypotension, heart block, metabolic acidosis and seizures.

Treatment

If there is gastric dilatation due to oxygen, a Ryle's tube should be inserted to decompress it. Otherwise, the management is symptomatic.

27.1 Basic Considerations of Environmental and Occupational Diseases

Randeep Guleria

INTRODUCTION

Environmental and occupational health is emerging as an important discipline in medicine due to the change that is occurring in climate due to industrialisation and urbanisation. It is being increasingly recognised that environmental factors have an important link with many chronic and infectious diseases. Deaths from heart disease and respiratory illness increase during heat waves and many diseases such as malaria, dengue, chikungunya and cholera are sensitive to changes in the climate.

According to the World Health Organization (WHO), 'In its broadest sense, environmental health comprises those aspects of human health, disease and injuries that are determined or influenced by factors in the environment. This includes the study of both the direct pathological effects of various chemical, physical and biological agents, as well as the effects on health of the broad physical and social environment, which include housing, urban development, land use and transportation, industry and agriculture'. The WHO estimates that 24% of the global diseases burden and 23% of all deaths can be attributed to environmental factors. Also, environmental factors have a much bigger impact in developing countries than developed ones and this effect is seen much more in the vulnerable population like children and elderly.

Environmental medicine encompasses human illness or dysfunction that may occur due to environmental factors. Many diseases are affected by environmental factors. These include diarrhoea, lower respiratory tract infections, injuries, malaria, perinatal conditions, chronic obstructive pulmonary disease, coronary artery disease, lead toxicity and drowning. Illnesses that occur due to workplace environmental factors are termed as occupational diseases.

In a developing country like India, the burden of various diseases increases due to environmental factors. It is estimated that 94% diarrhoeal disease burden can be attributed to environmental factors like unsafe food, unsafe drinking water and poor sanitation and hygiene. Similarly, there is strong evidence in our country linking lower respiratory tract infection to indoor air pollution caused by the use of solid fields in household. Almost 42% of acute lower respiratory tract infections in developing countries are attributable to environmental factors. Besides this the close link between vector borne diseases and environmental conditions is well established. Also, factors like deforestation, increasing vehicular traffic, migration from rural to urban areas, decreasing water resources and inadequate drainage system are important environmental factors that contribute to infectious diseases.

Occupational diseases also form an important but often neglected part of human health. It is estimated that in India about 45,000 fatal injuries and 17 million non-fatal injuries occur due to occupational factors. It has been estimated that in India prevalence of silicosis is 6.2% to 34% in mica minors, 4.1% in manganese miners, 30.4% in lead and zinc miners, 9.3% in coal miners, 27.2% in iron foundry workers and 55% in state pencil workers. Also asbestosis occurs in about 3% of asbestosis miners and 21% of mill workers in India. Also, it is estimated that about 28% to 47% of textile workers are exposed to dust and suffer from byssinosis.

Broadly, environmental diseases could be caused by exposure to harmful and toxic agents through air, water, soil and food. Environmental exposure can cause or aggravate a number of diseases like asthma, dermatitis, etc. In many cases these disease do not have a unique presentation and can present to different specialties. Environmental diseases occurring through air pollution are a major cause of concern and their prevalence is increasing. The important environmental pollution consists of air pollution, water pollution and the recent emergence of E-waste which may be the crux of environmental diseases.

AIR POLLUTION

Air pollutants affect the human body through the inhalational route. There are more than hundred substances which pollute the air we breathe and that can harm human health. Pollutants are generally classified as primary or secondary pollutants. Chemicals which are directly emitted from a source are known as primary pollutants. These include sulphur dioxide, nitrogen oxides, carbon monoxide, volatile organic compounds, etc. Also particulate matter emitted due to combustion from a source such as automobile exhaust, heating, cooking and from industrial sources are primary pollutants. Secondary pollutants are those pollutants that are formed from a chemical or photochemical reaction in the atmosphere. On exposure to sunlight volatile organic compounds and nitrogen oxides reacts photochemically and after a complex series of chemical reactions produces pollutants which are harmful. Ozone is an important secondary pollutant and can produce significant adverse effects on human health. Other secondary pollutants include formaldehyde, nitric acid, and different aldehydes.

Sulphur Dioxide

Sulphur dioxide is produced mainly by burning of coal and by the combustion of fossil fuels in power plants. Sulphur dioxide is mainly absorbed in the upper airways as it is water soluble. Some of it reaches the lower airways and causes bronchoconstriction. It can therefore worsen asthma.

Nitrogen Dioxide

Nitrogen dioxide is emitted from automobiles. Nitrogen oxides play an important role in the reaction which occurs in the atmosphere and leads to the formation of ozone. They also form nitrate particles and acid aerosols. Exposure to nitrogen dioxide for a short term leads to changes in airway responsiveness

and deterioration in pulmonary function in individuals with underlying lung disease. Long term exposure may lead to increased chance of recurrent respiratory tract infections and alter lung mechanics.

Carbon Monoxide

Carbon monoxide is produced mainly due to motor vehicle emission. In urban areas more than 80% of carbon monoxide emission may be due to motor vehicles. Besides this, the combustion of coal, oil and gas also leads to carbon monoxide production. Carbon monoxide quickly enters the blood stream and forms carboxyhaemoglobin which causes more systemic effects. It reduces oxygen delivery to the tissues and may have a serious health threat to those with underlying heart disease.

Lead

The atmospheric levels of lead have decreased due to the use of unleaded fuel. However, lead toxicity continues to be a problem due to the exposure occurring in drinking water. Lead exposure leads to adverse effect on the central nervous system, kidney and liver. Lead toxicity can lead to lower intelligence, learning deficits and behavioural disturbances.

Ozone

Ozone is produced as a secondary pollutant and is a component of photochemical smog. Ozone is a pulmonary irritant and an oxidant. Exposure to ozone causes cough, chest tightness and wheezing. It also leads to a decline in lung function. Ozone also affects mucous membrane and causes pulmonary inflammation and has both a local and systemic effect on immune system. Patients with underlying respiratory illness like asthma and chronic obstructive airway disease are more prone to the harmful effect of ozone. High ozone concentrations have been linked with increased hospital admissions for pneumonia, COPD and asthma.

Particulate Matter

Particulate matter consists of liquid or solid mass contained in an aerosol. It is a mixture of numerous different chemicals with varying properties. Particulate matter was initially expressed as total suspended particulates (TSP). Subsequently the term PM_{10}, i.e. suspended particulates with a mean aerodynamic diameter of 10 microns or less was used. It was later realised that still finer particulate matter can be harmful and the term $PM_{2.5}$, i.e. particulate matter with a mean aerodynamic diameter of 2.5 or less was used. Broadly particulate matters from 2.5 microns to 10 microns in diameter are coarse particulate matter. Coarse particulate matter consists of mainly of airborne soil dust and elements such as silicon and aluminium. Fine particles are those with a diameter of less than 2.5 microns. They are formed mainly from combustion or from photochemical reactions and are composed mainly of sulphate and organic material. Particles of more than 10 microns are mainly filtered in the upper airways and do not reach the lower airways. Smaller particles between 2.5 microns to 10 microns reach the lower airway and are deposited there. Particles less than 2.5 microns go deeper and reach the alveolar region and cause damage in this area.

Indoor Air Pollution

Indoor air pollution has a significant effect on human health globally. This effect is more pronounced in developing countries. It is estimated that more than 60% of households in India use biomass fuels as energy source. Wood, roots, crop residue, cattle dung are amongst the biomass substances used for energy source. Biomass cooking converts 6% to 20% of the fuel carbon to toxic substances due to poor combustion. The harmful air pollutants that are emitted by using biomass fuel include carbon monoxide, particulate matter, hydrocarbons, oxygenated organics and chlorinated organic compounds. There is now a strong evidence linking indoor air pollution exposure to a number of illnesses especially lung diseases. Indoor air pollution is linked to acute lower respiratory tract infection. In adults there is a strong association of indoor air pollution and chronic obstructive lung disease especially in women who start cooking in rural areas at an early age. Also, there is evidence to suggest that biomass exposure in pregnant women may lead to an increase in low birth weight neonates and increased chance of still births. There is also some epidemiological evidence linking exposure to indoor air pollution to lung cancer and tuberculosis although the association is not that strong. Biomass exposure also significantly contributes to fine particulate matter exposure, i.e. $PM_{2.5}$. Exposure to $PM_{2.5}$ may lead to a higher chance of lower respiratory tract illness and still births in pregnant women.

WATER POLLUTION

Water is essential for human survival. Water pollution constitutes another serious risk to health. Water pollution occurs when energy and substances are released and that degrades the quality of water for other users. Anything that is added to water that is more than its capacity to break it down constitutes water pollution. Chemical pollution of surface water causes major health problems as it can be used directly for drinking or it may contaminate shallow wells which are used for drinking. Usually, it is human action which is responsible for water pollution, although it may occur naturally as happens when water flows through soil with high acidity. Ground water, which is much deeper, has very few pathogens as it gets filtered when it passes through many underground layers. It can be polluted by toxic chemicals like fluoride and arsenic which may be present in the soil or the rock layers. Similarly, pollution of coastal water can cause contamination of sea food. The global effect of water pollution has not been studied in detail, and is limited to mainly outbreaks of waterborne infections or certain chemical toxins in limited areas, i.e. arsenic in drinking water in Bangladesh, mercury poisoning in the United States, etc. Acute exposure to contaminated drinking water can cause inflammation to the eyes, skin and the gastrointestinal tract. Chronic exposure to contaminated water can cause significant health effects and can lead to liver and kidney damage. This occurs due to chronic exposure to copper, cadmium, arsenic, mercury, chromium and chlorobenzene. Endocrine effects have been reported and problems relating to reproduction, development and behaviour have also been observed.

ELECTRONIC WASTE (E-WASTE)

Pollution due to electronic and electrical waste has rapidly grown over the last decade. Waste which is generated from used electronic devices and household appliances constitutes E-waste. This waste comprises of a wide range of equipments and devices such as computers, mobile phones, refrigerators, washing machines, air conditioners, etc. E-waste may contain many toxic substances which may be harmful to the environment and human health. This can have a significant

economic and social impact on society. The E-waste obsolescence rate in India for 2005 was estimated to be 1,46,180 tonnes, and it is estimated that this will exceed 8,00,000 tonnes by the year 2012. A large number of hazardous substances can be found in E-waste. These include lead, cadmium, chromium, mercury and plastics. Uncontrolled burning, disposal and dismantling of E-waste can cause a number of problems including air pollution and water pollution. There is a lack of an environmentally effective recycling infrastructure for E-waste and this leads to pollution of the environment. There is, therefore, a need to increase public awareness about the harmful effects of E-waste and develop an effective recycling and disposal plan to prevent or minimise air and water pollution.

CONCLUSION

It is important to understand that environmental and occupational health problems will have a number of acute and chronic effects on human health. This can be both for infectious and non-infectious illnesses. A holistic view is needed to address the problem of environmental health where agriculture, animal husbandry, public health, water safety and air pollution need to be looked at in a combined manner for education, planning and resource allocation. A close team work between scientists, public health professionals and administrators is needed for integrated vertical and horizontal planning.

For clinicians an awareness about the health effects of pollution is important as this will help in the prevention and proper management of many diseases associated with both air and water pollution.

27.2 Climate Change—Health and Disease

Anil Gurtoo

INTRODUCTION

Our planet, Earth, which is some 4.5 billion years old, has been through at least 5-mass extinctions. The first extinction is known as Ordovician (439 million years back) and this was followed by Devonian (354 million years), Permian-Triassic (252 million years), Cretaceous-Tertiary (65 million years) and Paleocene-Eocene Thermal Maximum (PETM) 55 million years ago. All these species extinctions are thought to be triggered by global climate change. The worst happened during the Permian-Triassic extinction event, which is also known as 'the great dying', when some 90% of marine and 70% of land species were wiped out, consequent to a large scale build up of green house gases (GHGs) and a temperature rise of more than 8°C caused probably by a large scale volcanic eruption over Siberia. The most recent is the PETM, occurred some 55 million years ago as a result of sudden release of vast quantum of GHGs that triggered a surge in global temperatures of about 5°C to 8°C over a span of a few thousand years and lasted 100,000 years. The source of GHGs is speculated to have arisen from the destabilisation of beds of frozen methane hydrate sequestered at the ocean's bottom. The release of frozen sea bed methane was probably triggered by an anomaly in the thermo haline circulation (THC) that pushed down warm waters leading to the release of sea bed methane (a green house gas with a warming potential 25 times of carbon dioxide).

ANTHROPOGENIC CLIMATE CHANGE

In the landmark study of temperature change, *Charles Keeling* in 1958 began recording monthly carbondioxide (CO_2) levels at Mauna Loa observatory, atop a 3,970 m high extinct volcano in Hawaii. Measurements taken over the past 50 years reveal two superimposed trends.

(i) A progressive rise in CO_2 levels from 275 ppm in 1958 to 385 ppm at present, and

(ii) Superimposed upon the rising CO_2 curve, a sharp annual rise and fall in CO_2 by about 50 ppm. This see-saw corresponds to the thickening and thinning of the photosynthesising green cover on account of seasonal shedding (winters) and gaining (summers) of green leaves in the Northern Hemisphere.

This gave rise to the famous Keeling's Curve: The annual see-saw atop a steadily rising CO_2 concentrations. In parallel to the rising CO_2 the average surface global temperature has already increased by 0.76°C above the pre-industrial levels and the sea-level by 4 cm (is rising at 3 mm/year). The Intergovernmental Panel on Climate Change (IPCC) was formed in 1988, it states that the evidence for global warming is unequivocal and is due to human activity (anthropogenic).

The Green House Effect

If our Earth lacked its gaseous atmosphere, all the incoming solar energy would be radiated back in to the space and the average surface temperature would plunge to –18°C. However, on account of the heat trapping effects of atmosphere, the Earth's surface temperature averages at 14.4°C. This is called the 'green house effect'. Out of the total sunlight that reaches earth:

1. About 30% gets reflected back to the outer space by reflectivity of bright surfaces such as low level clouds, dust, snow and ice. This reflective property of bright/white surface is called 'Albedo' and is a factor in cooling. Conversely, darker surfaces like ice-cleared sea absorb the incoming solar energy and are a factor in warming (low albedo).
2. More than 20% of sunrays are absorbed by the atmosphere mainly by water vapour.
3. The remaining 50% is absorbed by the Earth's surface – land, forests and oceans. Of this 50% is absorbed by the Earth, a third or so is re-radiated back as infrared waves (heat waves). Most of this radiated infrared is absorbed by the green house gases (GHGs) present in the atmosphere, which then radiate some of it to the outer space and some back to the Earth, thus keeping the mean surface temperature warm at 14.4°C.

The Green House Gases

The main GHGs are CO_2, methane, water vapour, ozone, nitrous oxide (N_2O) and chlorofluorocarbons.

Carbondioxide

CO_2 forms some 0.04% of the atmosphere and is the main green house gas. Its present concentrations are the highest ever recorded at 384 ppm, and rising by 1 ppm to 2 ppm per year as a consequence of human activities. Historical data from the 650,000 year old ice-core samples from Vostok, Antarctica reveal that atmospheric CO_2 levels have always held constant between 180 ppm (during ice-ages) and 280 ppm for most of our Earth's geological past. While the natural CO_2 is produced by the decomposition of dead organic matter and exhalations of humans and animals, the anthropogenic CO_2 is generated mainly by the combustion of fossil fuels (coal, oils and gas) and land clearing for agriculture. Of the total CO_2 thus released to atmosphere, nearly 50% is absorbed back by the natural sinks: the oceans and the land (chiefly by plant photosynthesis) in an equal measure of 25% each. The remainder stays up in the air as a green house gas for nearly 100 years.

Methane (CH_4)

It is a far more potent GHG with a warming potential 25 times that of CO_2. But its residence time is only 10 years and its atmospheric concentration has stayed low at 2 ppm. In nature it is produced from the livestock (aerodigestive processes), decaying organic matter, and the anthropogenic component is generated by: untreated sewage, industrial actions, rice cultivation, livestock rearing and land fills.

Water vapour

Though a weak GHG, it acts mainly as a force multiplier through a positive feedback effect wherein, as the temperatures rise, more and more of vapour gets released due to enhanced evapotranspiration, this extra-vapour in turn further enhances the warming, which in turn further increases the amount of vapour. Such a spiralling signal enhancement (temperature rise) is termed as positive feedback effect.

Ozone (O_3)

Ground level (harmful) ozone is produced when sunlight acts upon the aerosols present in the stagnant air masses and smog. It is this ground-level ozone that causes the excess cardio-respiratory mortality. Its concentration has stayed fixed at 0.03 ppm and has a residence time of only a few days. Quite the contrary, the high level (stratospheric) of ozone acts as a shield to the harmful UV light. It is here that its decrease (ozone hole) due to anthropogenic CFCs, leading to an increased influx of UV radiation.

Nitrous oxide (N_2O)

It is present in concentrations of 3 ppm, but with a warming potential 300 times of CO_2 and a residence-time of 300 years. In nature, it is produced mainly by lightening thunders and soil bacteria, whereas, its anthropogenic sources lie in diesel based combustion and fertiliser use.

Chlorofluorocarbons

Produced as a result of human actions (refrigeration, aerosol products), these are extremely potent with warming potentials 124 to 14,800 times of CO_2 (hydrofluorocarbons); 7,400 to 12,200 times of CO_2 (perfluorocarbons); and 22,800 times of CO_2 (sulphur hexafluoride). They form around 1 ppm of the air but are extremely long lived. They have been responsible for the causation of ozone hole.

HEALTH EFFECTS OF CLIMATE CHANGE

The health impacts resulting from climate change can be framed in terms of an integrated model centred on the 'epidemiological triangle' is conceptualised in **Figures 1 and 2**. The key variables are displayed in **Figure 1**, while **Figure 2** displays the 'upstream domains' which stress the epidemiological triad and destabilise it. The 'downstream domains' depict the health outcomes and their socioethical implications.

Tipping Points

A term that refers to a critical threshold, beyond which even a minor perturbation can lead to the emergence of a new state.

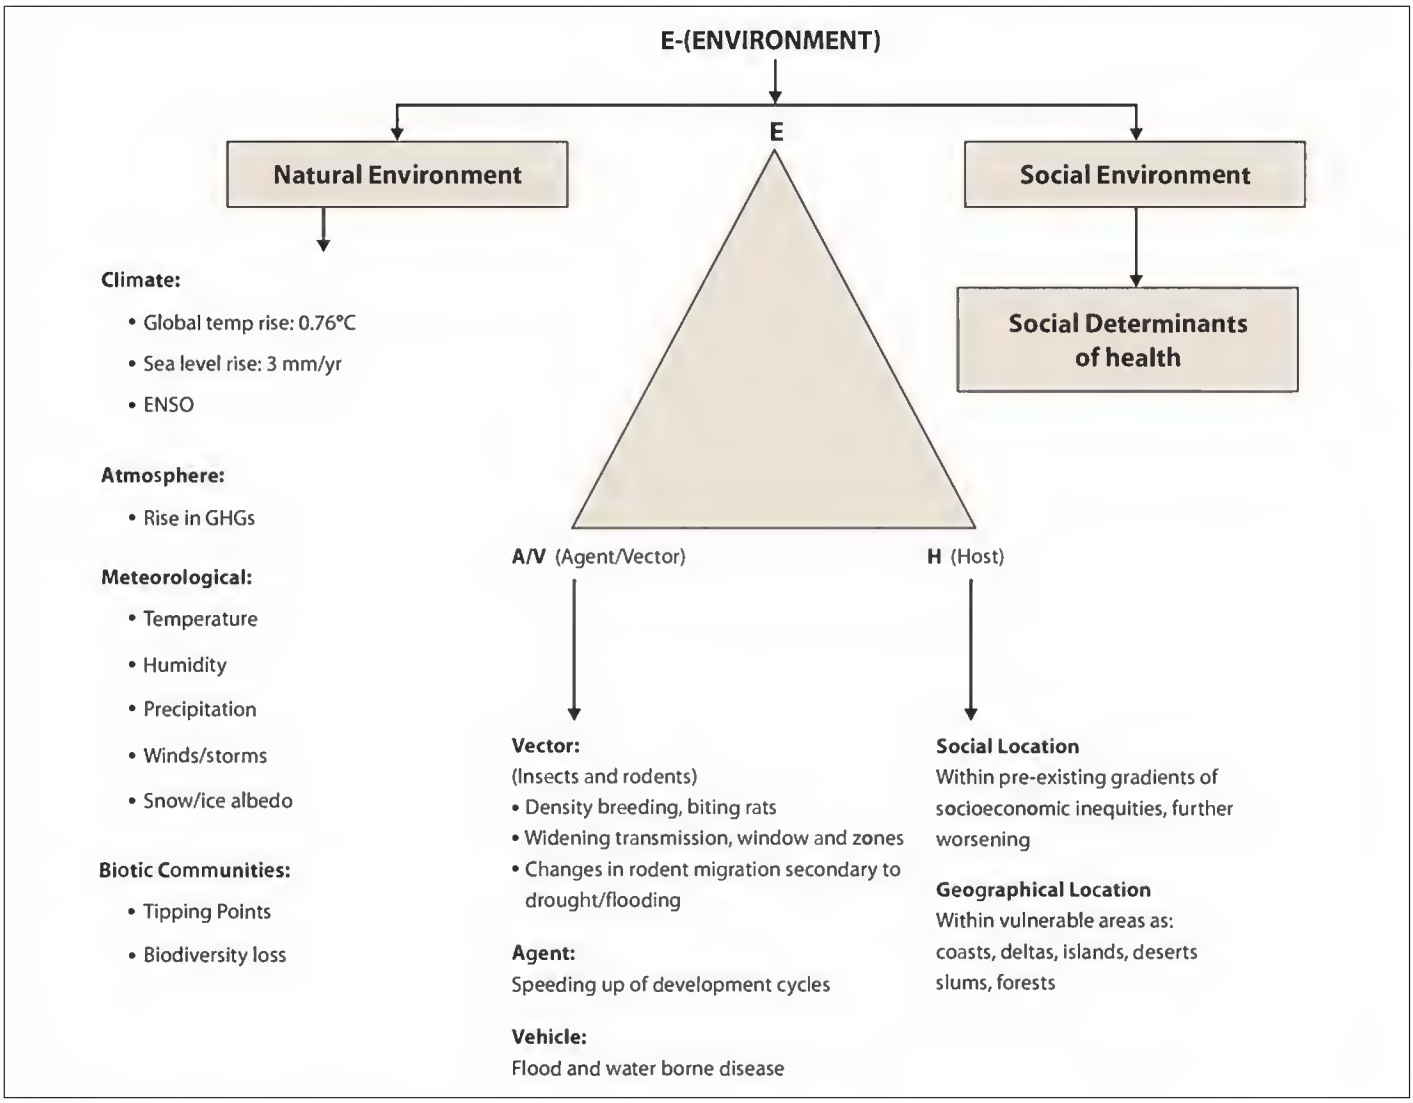

Figure 1: The epidemiological triangle of climate change and its health effects.

ENSO = EL-Nino Southern Oscillation; GHGs = Green House Gases.

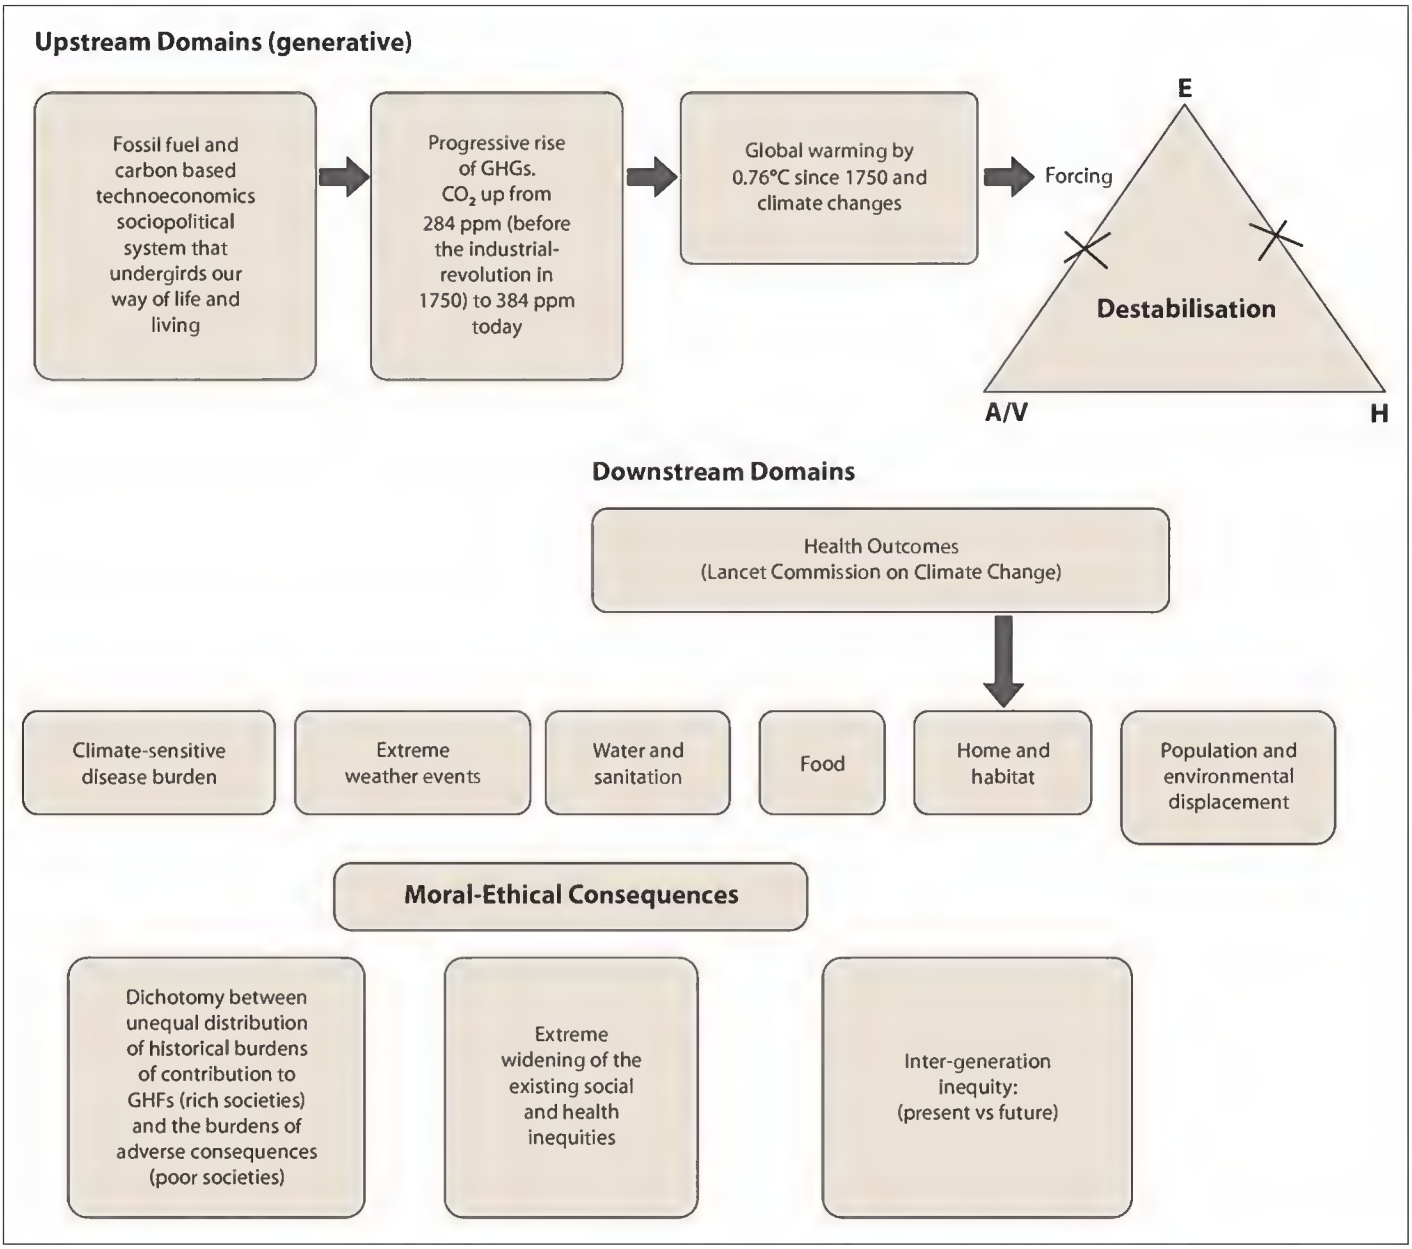

Figure 2: Upstream and downstream domains responsible for destabilisation of epidemiologic triangle.

Once a tipping event is triggered after the crossing of the tipping point or threshold, there is no turning back, even if all the GHG emissions were to end.

Lenton *et al* have identified several sectors of Earth's ecological systems that might cross the tipping points leading to non-linear outcomes including several orders of magnitude larger than predicted by current models (**Table 1**).

Table 1: Important Tipping Points in the Climate Change and their Consequences

S. No.	Tipping Event	Consequences
1.	Loss of Arctic Summer Sea ice	Higher average global temperatures
2.	Greenland ice sheet meltdown	Global sea level rise up to 7 m
3.	Collapse of West-Antarctic ice shelf	Global sea level rise up to 5 m
4.	Increased frequency and intensity of El-Nino events	Increased droughts in South Asia and Africa
5.	Amazon rain forest die-back	Massive species extinctions, decreased rainfall, massive loss of carbon-sinks
6.	Changes in Indian Monsoon System (Strengthening El-Nino will weaken monsoons)	Widespread drought
7.	Collapse of thermo haline circulation	Extremes of winters and summers over Europe
8.	Thawing of Tundra's permafrost	Meltdown and release of frozen methane hydrates

PATTERNS OF CLIMATE SENSITIVE DISEASES

The added burden of climate change sensitive diseases will further worsen the already existing health inequities creating enormous challenges to public health. Though complex and interdependent, for clarity's sake, one could divide the resultant health outcomes as: (1) direct; and/or (2) indirect impacts of climate change.

Direct Health Impacts

Results from extreme weather events such as heat waves, sudden flooding, storms and cyclones, droughts and inundation due to

sea level rise. All of these events are set to increase in both amplitude and frequency as a consequence of climate change. A partial glimpse of some recent extreme events is given in Table 2.

Table 2: Recent Extreme Events of the World

Place	Event/Consequence
Andhra Pradesh heat wave, 2003	Killed 1,421 people
Orissa heat waves, 1998 & June 2005	June 2005, Bhuvaneshwar recorded a high of 46.3°C. In year 1998, the heat wave claimed >1,000 lives
Mumbai, India, July 2005	Heaviest rainfall ever recorded in a single day in the last 100 years: 944 mm.
Pan-India monsoon deficit induced droughts	Recurring Monsoon deficit-induced serious droughts: 2000-2002, 2009.
Cherrapunji, Meghalaya, 2005	The world's wettest place went through a rain deficit-induced drought
European heat wave, 2003	Caused 70,000 deaths

Scanning through the European heat mortality data, a question begins to form; how could a simple heat spell of 35°C to 40°C end up killing 70,000 people? Clearly, the heat wave need not have to be extreme in order to kill. This phenomenon of multiplier effect (disproportionately wider and stronger health impact) may well hold true for most other climate sensitive diseases.

In the Europe of 2003, it was a combination of a sequence of hot days coupled with unusually hot and humid nights, cityscapes built for a cooler weather and a population culturally and physiologically un-acclimatised to heat that contributed to the multiplier effect. Indeed, most of the heat mortality seems to be a function of higher night time minimum temperature, duration of heat wave, pre-existing background vulnerabilities (extremes of age, cardio-respiratory disease and poverty), amount of ozone and PM-10 in the near ground stagnant air pollution, and heat island effect. More than the day time maximum, it is the night time minimum which determines the degree of heat stress. According to IPCC, the 12 warmest years in the past 150 years have been during the last 13 years with 1998 being the warmest, followed by 2005, 2002, 2003 and 2004.

Defining heat wave as a stretch of at least 5 days with highs of 5°C above average, IPCC estimates that the heat waves are likely to become more frequent and longer across most of the planet, especially towards the middle and upper-middle latitudes involving the central and southern Europe, the Western USA and Eastern Asia.

Indirect Effects on Health

Climate-sensitive diseases share some epidemiologic commons.

1. They display indirect transmissions employing either a vector (mosquitoes, ticks, fleas, flies), or a vehicle (water or food borne).
2. Insects being cold-blooded, a minor change in temperature can amplify into a large biologic effect on disease transmission. Therefore, climate change can act as a force multiplier and alter the incidence, seasonal transmission windows and the geographic range of diseases such as malaria, dengue, chikungunya, yellow fever, filaria caused by mosquitoes and leishmaniasis by sand fly.
3. Their distribution is determined by ecological synergies between a set of variables such as temperatures, rainfall, humidity, flooding or drought, sea level rise, phytoplankton and algal blooms on sea surface, EL-Nino Southern Oscillation (ENSO) and changes in water salinity. Rodent migratory behaviour is often dictated by changes in food sources, cropping patterns, grain storage, flood or drought induced displacements.
4. The extrinsic incubation period of an infective agent within its vector is sensitive to changes in temperature and humidity.
5. If both the agent (Plasmodium) and the vector (Anopheles) are competent and robust in the newly warmed and humid climate, then both will multiply and spread very rapidly giving rise to sudden emergence of explosive epidemics.
6. Like the climate itself, malaria incidence too displays a non-linear threshold—tipping point response in reaction to minor temperature changes.
7. The growth of mosquito and parasite population densities in response to warming can be several orders-of-magnitude larger than what the unit change in temperature would suggest.
8. Some scientist has demonstrated that, just half-a-degree centigrade increase in temperature can amplify into a 30% to 100% increase in mosquito population.
9. Likewise, the Lancet-UCL Climate Change Commission believes that a small increment in the risk for climate-sensitive diseases such as diarrhoea, malnutrition, dengue, etc. could snowball into disproportionately large increases in total disease burden.
10. As regards to the possible epidemiologic behaviour of malaria in India, WHO estimates that: (a) 10% more states may offer breeding-favourable climatic conditions throughout the year with respect to base year 2000; (b) transmission windows for malaria are likely to increase in the North and North-Western areas from the present 4 – 6 months to 7 – 9 months; and that (c) by the year 2080, malaria may move up in altitude up to elevations of 1,800 m.
11. Dying or drying rivers often fragment into a series of stagnant pools that serve to increase mosquito breeding rates.
12. Counter intuitively, a drought or drying may actually trigger mosquito-based epidemics. Drought and water shortages often trigger social behaviours that lead to increased water storage in household containers that increases the density of peri-domestic dengue transmitting Aedes mosquito. In fact, the chikungunya outbreak of 2004 that began in drought-affected Lamu in coastal Kenya and spread to India via the islands of Indian Ocean, also displayed climate-sensitivity.
13. Climate phenomena such as: EL-Nino events and the resultant sea surface warming are also linked with the emergence of cholera epidemics. *Vibrio cholerae* thrives in warm, saline sea waters in association with the floating

blooms of zooplankton and phytoplankton (which themselves proliferate with the warming seas). In Bangladesh, seasonal plankton blooms in the Bay of Bengal are correlated with sea-surface warming and the emergence of cholera outbreaks. Few scientists reported a strong correlation of inter-annual variability of cholera with (1) sea surface temperatures in Bay of Bengal; (2) EL-Nino Southern Oscillation (ESNO); (3) the extent of flooding in Bangladesh over short periods of <7 years; and (4) monsoon rains and Brahamputra river discharge over longer periods of >7 years. Similar finding was also reported from Lima, Peru where EL-Nino induced winter time warming of 5°C during 1997-98, was correlated to >200% daily admissions for diarrhoea as compared with the baseline. In fact, they observed that with every 1°C rise in air temperature above normal, there was an 8% increase in hospital admission rates for childhood diarrhoea.

CLIMATE-SENSITIVE HEALTH BURDENS

WHO believes that climate change has been responsible for 5.5 million disability adjusted life years (DALYS) lost in 2000 on account of diarrhoea, malaria, malnutrition and accidents due to extreme weather events.

Heat Stress

The IPCC in 2007 made projections that superimposed upon the global rise in mean surface temperature and there will be trend of extreme variability leading to frequent and intense heat waves. While the phenomenon of excess mortality resulting from heat waves is well recognised, warmer than average temperatures *per se* are also associated with higher mortality rates. Most of this vulnerability will be located in cohorts with poor adaptive capacities such as: the older age and the very young, the urban poor, those with chronic medical conditions (particularly, cardiovascular and respiratory diseases), and in the socially isolated. Infact Curiero and Mc Michael *et al* have characterised the relationship between temperature and mortality as a: 'J-shaped curve', such that the mortality increases with both colder and warmer temperatures beyond a certain optimal temperature at which it is the lowest. During the 2003 European heat wave, IPCC (2007) estimates that while France experienced 15,000 excess deaths, the total for Europe was estimated to be 35,000 excess deaths. Also IPCC expects a rise in frequency and intensity of global warming triggered extreme weather events (cyclones, flash floods and droughts) which will adversely impact public health through a combination of direct and indirect effects.

Changes in Climate-Sensitive Infectious Disease Burden

Climate change is not likely to result in the emergence of new or unforeseen diseases but an exacerbation of the existing disease burdens engendered through a redistribution of the classic determinants of health such as air, water, food, shelter, temperature and humidity. Of particular concern are the vector borne diseases which are bound to expand across geographical range due to climate change-induced alterations.

Malaria and Climate Change

Climate change increases malaria transmission by amplifying growth enabling factors such as the optimum temperature windows between 15°C and 39°C for the favourable development of both the vector (mosquito) and the parasite (plasmodium). Global warming will ensure that the transmission windows for malaria will remain open for 10 to 12 months in much of the central, coastal and north-eastern India from the present duration of 6 to 7 months.

Ambient Air Pollution

Tropospheric (ground level) ozone production is forecast to increase as a function of rising average temperatures (IPCC, 2007). Ozone is formed via sunlight driven photo-chemical reactions involving nitrogen oxides and hydrocarbon precursor aerosols. Warmer temperatures are known to amplify these ground level ozone generating reactions. Fossil fuel burning also worsens the particulate air pollution. Both ozone and particulate matter air pollution have been associated with increased risks of mortality and morbidity resulting from the respiratory and cardiovascular events (WHO, 2006).

27.3 Environmental Pollution

Ashok A Mahashur

Industrialisation and urbanisation have resulted in the deterioration of urban air quality. Amongst the environmental pollution, air pollution is most deleterious to the respiratory system as the pollutants are inhaled directly into the respiratory tract. The sources of air pollution are vehicular emissions and indoor industrial smoke.

'Air pollution' comprises of a diverse nature of chemical emissions including gaseous combustion products, volatile chemicals and aerosols (particulates). The most common pollutants are ozone, carbon monoxide, sulphur dioxide and nitrogen dioxide.

OZONE

Ozone gas is a very strong oxidant, reacting with biomolecules to form ozonides and free radicals. The ozone-induced inflammation is mediated from prostaglandins (PGE_2, PGF_2, TXB_2), neutrophils, fibronectin, interleukin-6, cytokines, etc. These lead to increased airway permeability, macrophage function impairment leading to increased susceptibility to bacterial infection.

Ozone has different health implications in stratosphere and troposphere. In the stratosphere (ozone layer) 10 to 15 km above the earth, ozone presents a critical barrier to solar ultraviolet radiation and prevention from skin cancers, cataracts, etc.

Symptoms

Ozone-induced illnesses include conjunctival irritation; lower respiratory tract irritation, cough and shortness of breath, wheezing, reduced tidal volume, nausea, malaise and headache. It also causes a peculiar type of pain which is substernal, mainly tearing or burning in character which is more severe during inspiration. Asthmatic children playing outdoors are roughly 20% to 40% more likely to suffer from asthmatic exacerbation. Ozone leads to impairment of pulmonary function and increased hyper-reactivity of airways. Persons at risk include asthmatics, chronic obstructive lung disease (COLD) and those who are active outdoors for prolonged periods like athletes, policemen, labourers, construction workers, etc.

PARTICULATES

More than 70% of the population in the world lives in areas with high particulate levels. The particulate air pollution is a heterogeneous classification of liquid and solid aerosols which include emissions from fuel combustion (coal, oil, and biomass), transportation and high temperature industrial processes. The large particles above 10 microns get deposited in the nasal and tracheobronchial regions and smaller particles less than 10 microns penetrate directly into the lungs.

Symptoms

Acute signs and symptoms include restricted activity, respiratory illnesses and exacerbation of asthma and chronic obstructive pulmonary disease (COPD). The group at large-risk includes the elderly and persons with chronic heart and lung diseases. There is reduced pulmonary function leading to increased morbidity due to respiratory illnesses and cardiac illnesses.

CARBON MONOXIDE

Carbon monoxide (CO) exposure is usually high due to local accumulation of CO in heavy traffic. Indoor levels are generally low in the absence of strong indoor sources.

Sources of CO exposure include inside passenger car, proximity to busy roads, constructions site parking areas and traffic tunnels. Their important contributors include traffic volume, traffic speed, and winter season.

Health Effects

Health effects are due to decrease in oxygen carrying capacity of blood and disruption of cytochrome function. The symptoms usually consist of headache, fatigue and flu-like symptoms. Risk groups include smokers and those with coronary artery disease (CAD), peripheral vascular disease and COPD. Adverse cardiac effects include decreased exercise capacity, arrhythmias, etc.

SULPHUR DIOXIDE

Sulphur dioxide (SO_2) gas is formed during combustion of sulphur containing fuel (coal and oil). The major health effects are breathing difficulty, respiratory illnesses, alteration in pulmonary defences and aggravation of existing cardiovascular disease. Children, elderly persons and persons with asthma, cardiovascular disease and chronic lung disease are more susceptible to adverse health effects associated with SO_2. The SO_2 reacts in the atmosphere to create sulphuric acid (H_2SO_4) and form acid aerosol (acid rain).

NITROGEN DIOXIDE

Nitrogen dioxide (NO_2) is released from fossil-fuel combustion. It reacts in the presence of sunlight and VOCs to form ozone gas and contributes atmospheric reaction to the formation of nitrous and nitric acid aerosols.

Health Effects

It is absorbed in both large and small airways. Their high concentration (more than 200 ppm) is very dangerous causing lung injury, fatal pulmonary oedema and bronchopneumonia. Lower concentration causes impaired mucociliary clearance, particle transport, macrophage function and local immunity.

AIR TOXICS

Toxic air pollutants is a term applied to certain volatile chemicals, pesticides, herbicides, metals and radio nucleotides, released in atmosphere by various industrial processes. They reach the general population by direct pulmonary assimilation.

Diagnosis

Diagnosis of respiratory illness related to ozone, NO_2 particulates, SO_2, diesel, and air toxics is clinical and presumptive, based on a history of elevated community pol-lutant levels, especially in combination with prolonged exposure outdoors with elevated workloads. The soft clues include an association with typical symptoms (ocular and upper respiratory irritation, chest pain, shortness of breath, cough, wheezing, nausea, malaise, headache), and signs (conjunctival and upper respiratory inflammation, pulmonary inflammation or infection, wheezing, prolonged expiratory phase). The chest pain associated with ozone exposure is characteristically exacerbated during inspiration and relieved during expiration, resulting in a decreased tidal volume. Forced expiratory volume in the first second (FEV_1), forced vital capacity (FVC), and diffusion lung capacity for carbon monoxide (DLCO) may be reduced and methacholine responsiveness may be increased.

Differentiation from other common causes of respiratory illnesses is not well defined, and several aetiologies may contribute to an individual's illness. Similarly, atmospheric concentrations of multiple pollutants often fluctuate simultaneously, making precise aetiologic differentiation rarely practical.

INCINERATORS POLLUTION

Particulate and gaseous emissions from municipal solid waste incineration depend on the waste stream composition and incinerator engineering and operation, but typically include heavy metals (Hg, Pb, As, Cd, Cr, Mn, Ni, Sb, Se, Zn, V), polychlorinated dibenzodioxins, dibenzofurans, and polycyclic aromatic hydrocarbons, in addition to acid gases and oxides of nitrogen, sulphur and carbon. Batteries, fluorescent light bulbs, magazine dyes, papers, plastics are sources of metals; lead and cadmium are emitted mostly in the particulate fraction, while mercury is more in gaseous form. Incinerator ashes contain high concentrations of metals. Chlorine and fluorine are emitted as acid gases, and contribute to halogenated aromatic organic compound formation. Proximity to incinerators has been associated with local lead soil distribution; the association of dioxin exposure with incinerators is less consistent. The major route of dioxin ingestion is in animal fat foods (milk, eggs, animal flesh), although plant deposition and inhalation contribute small amounts. Dioxins have also contaminated herbicides which are widely sprayed along highways and rail-road right-of-ways. Nonetheless, cow's milk may be more contaminated with dioxins near municipal solid waste incinerators. A recent ecological study found stomach and lung cancers to be elevated in communities near municipal solid waste incinerators in Great Britain. This preliminary and unconfirmed finding is an outcome of concern in light of parallel cancer elevations in a study of MSW workers. Increasing attention is being paid to dioxin and mercury emissions from medical waste incinerators.

DIESEL AND AUTOMOBILE EXHAUST/HEALTH EFFECTS

Diesel exhaust contributes to ambient sulphur oxides, ozone precursors, and aerosols, seems to contribute to chronic respiratory morbidity and mortality and probably contributes to the cancer risk of urban air pollution. Mutagenic and carcinogenic compounds (such as PAHs) are adsorbed to diesel soot.

In humans, occupational case control and cohort studies have found a small but generally consistent association of prolonged exposure to high diesel concentrations, when adjusted for cigarette smoking, with a relative risk (RR) of lung cancer incidence of 1.4 to 1.7 in the best studies. While most studies have problems with exposure assessment, wide confidence intervals and low effect magnitude. A recent meta-analysis of over 20 studies examining occupational exposure to diesel exhaust, confirmed a statistically significant RR of 1.33 for lung cancer, with adjustment for cigarette smoking.

Heavy exposure to diesel is clearly associated with pulmonary inflammation, with some evidence of increased incidence of respiratory symptoms (cough, phlegm, and wheezing) and small work shift pulmonary function decrements; heavily exposed cohorts may have elevated risks of mortality from chronic lung disease (COPD and respiratory infection).

Acute Respiratory Effects

Four acute respiratory effects of air pollution are well established; asthmatic attacks, hyper-reactive airways, respiratory infections, and reversible changes in lung functions.

Asthma is a condition in which the airways suddenly narrow, obstructing the flow of air through the lungs. The narrowing is caused by spasms of the small muscles that encircle the airways and by the release of thick, excessive mucus that plugs them. Air pollution can bring on asthmatic attacks. Attacks have also been associated with ozone and particulate pollution. In areas surrounding power plants and smelters, SO_2 and sulphate particulates cause bronchospasm. It is not known whether air pollution can actually cause asthma or whether it only triggers asthmatic attacks.

Hyper-reactive airways are those that constrict much more readily than average in response to foreign matter. Unlike asthma, some constriction of the airways is a normal defence mechanism to prevent inhaling noxious substances in persons with hyper-reactive airways. The airways respond to levels that do not bother most people. The symptoms are similar to asthma—shortness of breath, coughing, and wheezing. SO_2 particulates, ozone, and NO are known to stimulate airway reactivity.

The incidence of respiratory infections, particularly in children, is increased by air pollution. Upper respiratory infections, such as cold, influenza and sore throat are associated with sulphate, sulphur dioxide, and particulates in outdoor air. NO_2 released indoors by cooking gas stoves, is associated with more frequent cold in children under the age of 10 compared with children who live in homes equipped with electric appliances. Animal studies show that concentrations of ozone and NO_2 typical of peak pollution episodes lower the resistance to bacterial infections such as pneumonia and acute bronchitis. Air pollutants disable the clearance mechanisms that remove viruses and bacteria from the respiratory tract and incapacitate the cells that fight the infections.

Short-term, reversible changes in lung function are also caused by air pollutants. For example, the maximum amount of air that can be inhaled or exhaled in one second is reduced in both children and healthy adults when exposed to elevated pollutant concentrations, but this returns to normal when exposure ceases. Whether such changes indicate that long-term damage is being done is not known at present.

Chronic Respiratory Effects

The two chain effects of long-term exposure to air pollutants, aside from lung cancer, are COPD and changes in the development and ageing of the lungs. COPD is actually a group of diseases that share the common symptoms of breathlessness. Because a clear-cut diagnosis is often impossible until after death, the conditions are grouped together. The group includes chronic bronchitis, emphysema, and small airways disease. Chronic bronchitis involves the persistent secretion of excessive amounts of mucus into the airways; its leading symptom is a lasting phlegmatic cough. Emphysema is a destruction of the wall of the air sacs (alveoli) and is indicated by breathlessness without cough. Small airway disease involves inflammation and narrowing of the smallest airways (bronchioles) and is the earliest sign of smoking-induced COPD. These diseases can appear separately or together. The long-term survival is influenced strongly by how susceptible the individual is to respiratory infections such as influenza and pneumonia. About 10 million people in the United States of America are afflicted with COPD.

The main causes of COPD are smoking, occupational exposures to such substances as coal and cotton dusts, high concentration of SO_2, and particulates and genetic factors. Air pollution plays a role in several ways. Some evidence suggests that a history of respiratory infections during childhood may contribute to pulmonary disease in old age, and as previously mentioned, air pollution increases childhood infections. Air pollution has been linked to COPD in recent studies of Mormons, a group with a very low rate of smoking. The longer and greater the exposure to outdoor levels of SO_2 and sulphate particulates, the more prevalent and severe the disease symptoms. Studies in laboratory animals have shown that long-term exposure to NO_2 and ozone causes destruction of alveolar walls, similar to emphysema.

Lung growth is also affected by air pollution. The lungs typically grow until the age of 20, and then slowly decline in their ability to hold air with age. Slowed rates of lung growth have been observed in children aged 6 through 12 exposed to certain indoor air pollutants. The changes are greatest in homes with smokers. A smaller adult lung size means less reserve against the inevitable shrinkage of the lungs with old age and against the onset of obstructive pulmonary disease, which occurs more commonly at older ages.

Lung Cancer

Cancer of the lung is the leading fatal cancer among both men and women, responsible for over one-fourth of all cancer deaths. Smoking is the major cause of lung cancer. Air pollution causes some fraction of lung cancers, but exactly how much is in dispute. Some experts contend that air pollution causes only a small percent of all cases, while others argue that it is 20% or more. It is clear that carcinogenic compounds are present in indoor air and polluted outdoor urban air. Chemical analysis of air show the presence of cancer-causing by-products of burning such as benzo-[a]-pyrene and dioxins, fibres such as asbestos, and metals such as arsenic and cadmium. Toxicological studies show that extracts of polluted air can produce lung tumours in mice, rats, and hamsters and cause injury to the genetic material deoxyribonucleic acid. Studies in human populations have found increased cancer rates around smelters and factories, in cities compared to rural areas, and with duration of exposure to pollution.

The major question has been to what extent these materials alone have caused cancer compared with tobacco smoke. Tobacco smoke interacts synergistically with other carcinogens, including radon, asbestos, arsenic, and alcohol, to increase the underlying cancer risk. Many people who have never smoked are exposed passively to tobacco smoke either at work or at home. These and other problems blur the role of air pollutants in producing lung cancers. Nevertheless, there are estimates that between 5,000 and 20,000 cases of lung cancer per year are caused by radon, with most cases occurring among smokers.

Non-Respiratory Effects

Air pollution affects organs in the body other than the lungs. Once inhaled, pollutants can be absorbed into the blood stream and can reach all areas of the body. Air-borne lead has caused nervous disorders in children, including learning disabilities and hyper-activity, kidney damage leading to high blood pressure in both children and adults and outright poisoning. Lead levels have dropped dramatically in the last 15 years as leaded gasoline has been phased out, but deposits on the ground from earlier years are a lingering source of exposure.

Benzene is a cause of leukaemia in rubber and chemical workers and is present in the air from refinery operations and gasoline combustion. Benzene in outdoor air has been attributed to cause cancer. Various other organic solvents are associated with nervous system disorders in workers, but again, concentrations are so low that it is difficult to ascribe any particular cases to such exposures.

CO may play a part in the development of ischaemic heart disease, in which the heart muscle does not get enough oxygen over long periods and its tissues slowly die. Similarly, the added strain on the heart and lungs caused by a lack of oxygen during peak CO episodes when smoking cigarettes or when stuck in rush hour traffic may trigger heart attacks. While evidence of CO playing a widespread role in heart diseases is not conclusive at the moment, most experts think it is possible.

27.4 Air-Borne Pollutants and Smoke-Related Hazards

Rajeev Gupta

INTRODUCTION

Environmental toxins are major risk factors for disease. The Global Burden of Diseases Study has reported that unsafe water, sanitation and hygiene, indoor smoke from solid fuels and smoking tobacco use are the leading risk factors for mortality and disease burden, especially in low income developing countries such as India (**Table 1**). Urban outdoor air pollution, lead, global climate change, risk factors for injury, industrial carcinogens, air-borne particulates, ergonomic stressors and noise are other important environmental and occupational risk factors. In this chapter, we shall focus on some of these factors—outdoor air pollution, indoor air pollution from solid fuels, environmental tobacco smoke, occupational particulate matter and common industrial toxins.

Table 1: Risk Factors for Mortality and Burden of Disease Globally and in Developing Countries (Global Burden of Diseases Study)

Rank	Global		Developing Countries, e.g. India	
	Mortality	**Burden of disease**	**Mortality**	**Burden of disease**
1.	High blood pressure	Childhood and maternal underweight	Childhood and maternal underweight	Childhood and maternal underweight
2.	Smoking and tobacco use	Unsafe sex	Unsafe sex	Unsafe sex
3.	High cholesterol	High blood pressure	High blood pressure	*Unsafe water, poor sanitation and hygiene*
4.	Childhood and maternal underweight	Smoking and tobacco use	*Unsafe water, poor sanitation and hygiene*	*Indoor smoke from solid fuels*
5.	Unsafe sex	Alcohol	High cholesterol	Zinc deficiency
6.	Low fruit and vegetable intake	*Unsafe water, poor sanitation and hygiene*	*Smoking and tobacco use*	Iron deficiency anaemia
7.	High BMI	High cholesterol	*Indoor smoke from solid fuels*	Vitamin A deficiency
8.	Physical inactivity	*Indoor smoke from solid fuels*	Low fruits and vegetable consumption	High blood pressure
9.	Alcohol	Iron deficiency	Iron deficiency anaemia	*Smoking and tobacco use*
10.	*Unsafe water, poor sanitation and hygiene*	High BMI	Vitamin A deficiency	High cholesterol

BMI = Body mass index.

OUTDOOR AIR POLLUTION

Air pollution is an important determinant of population health. The World Health Organization (WHO) estimates that, at the global level, 1.4% of all deaths and 0.8% of disability-adjusted life years are the result of particulate air pollution. The short-term health effects of particulate and gaseous air pollutants have been well documented. A combined analysis of data from 124 large cities in Europe and North America reported an estimated increase in rate of deaths from any cause ranging from 0.2% to 0.6% for an increase in ambient small particle ($PM_{2.5}$) concentrations of 10 microgram per cubic metre. The long-term effects of exposure to major air pollutants (particulate matter, ozone, sulphates, sulphur dioxide, nitrous oxides, and carbon monoxide) have been well-documented in large cohort studies, and the second American Cancer Society Prevention Study reported an increase of 3% to 6% in mortality for every 10% change in air-pollution levels in USA.

Pollutants are generated from power plants, industrial complexes, automobiles and other vehicles and none of the pollutants occur in isolation. Pollutants change by chemical reactions after being emitted. Sulphur oxide can convert to acid sulphates and oxides of nitrogen and oxidants from automobiles react with sunlight to produce ozone. The symptoms and disease associated with air pollution are the same as conditions associated with smoking. Respiratory infections in children are associated with chronic exposure to traffic-related gases and respirable particles. Studies in urban locations in developed countries have reported higher cardiopulmonry hospitalisations and mortality. Pubic health measures such as stricter ambient air quality standards, publicising pollution alerts and avoidance of polluted areas have been useful to prevent and control the ill-effects of outdoor pollution.

INDOOR AIR POLLUTION

Indoor air pollution is due to widespread use of unprocessed solid fuels (biomass and coal) for cooking and space heating in India and other developing countries, often in unventilated situations. The 1991 Indian Census, for the first time, asked a question about the primary household fuel used and reported that at a national level 81% of households primarily used biomass fuel (dung, crop-residues and wood).

High pollutant concentrations result from emission factors from such fuels in simple small scale combustion devices and frequently result in high indoor air particulate concentrations that could lead to PM_{10} concentrations of more than 2,000 µg/m^3 in some households. It has been estimated that 400,000 to 550,000 premature deaths can be attributed annually to the use of such biomass fuels and indoor air pollution in India, mainly due to acute respiratory infections, chronic obstructive pulmonary disease (COPD), lung cancers, pulmonary tuberculosis, asthma and coronary artery disease (CAD) (**Figure 1**). This pollution also leads to frequent upper airways infections in subjects with and without underlying COPD and is a leading cause of disability-adjusted life years (DALYs) and high person sick-days in India. The pollution levels are more in urban than rural locations but can be very high in individual households. Exposure is not only the number of people involved, but also a function of frequency and duration of contact-person hours of exposure.

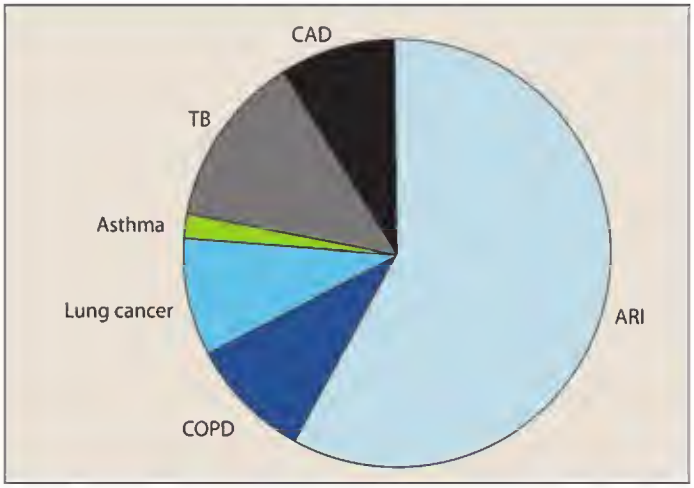

Figure 1: Estimated distribution of causes of annual death burden of 400-550 thousand due to indoor air pollution in India.

ARI = Acute respiratory infections; COPD = Chronic obstructive pulmonory disease; TB = Tuberculosis; CAD = Coronory artery diseose.

Salient features of indoor pollution in India and many developing countries as compared to developed countries are: (i) the biomass fuels produce relatively more organic compounds (e.g. benzene, formaldehyde, 1, 3-butadiene, polyaromatic hydrocarbons) and fossil fuels produce more sulphur oxides; (ii) chemical characteristics of the particles produced by biomass combustion are different; (iii) indoor pollutant concentrations are more during the day (because of household cooking) and place women and young children at greater risk; (iv) exposure levels in poorly ventilated biomass fuel areas are 10 to 50 times greater than urban outdoors in developed countries; (v) people exposed to indoor pollution in India are the poorest, most stressed and youngest as compared to other countries; (vi) implications on long-term health are unclear; (vii) misclassification of outcomes due to confounding by smoking exists; (viii) the attributable risk of indoor pollution on health outcome is difficult to quantify; (ix) there are no large scale data on the level of indoor air pollution in India using systematic sampling strategies; and (x) the estimates of mortality and DALYs are not well-defined. Therefore, it is essential that larger studies be conducted in India and other developing countries to better assess the role of indoor pollution.

At the global level, India seems to have some 30% of all household solid-fuel stoves, although the estimates are generally much less reliable than in India where fuel use is determined in the national census. On that basis, the total world health impact on women and children would be roughly three times larger than the Indian estimates. The alarming scale of toxicity of indoor air pollution argues for additional efforts to understand and ameliorate the conditions that lead to such severe pollution levels in the village and urban slum homes of India and elsewhere in the Third World. At the very least, they call for a serious effort to conduct the medical and abatement research that would pin down more accurately the impact of pollution and effective ways to reduce it.

ENVIRONMENTAL TOBACCO SMOKE

Smoking is rampant among Indian men and environmental tobacco smoke (ETS) should be an important health issue (**Figure 2**). The health hazards due to exposure to ETS are increasingly being established. ETS contains thousands of chemicals including 43 known carcinogens. Known health effects of ETS exposure are lung cancer in non-smokers, childhood disorders such as bronchitis, and perhaps, heart disease. Workplace exposure to ETS is widespread and is influenced strongly by the type of smoking policy in the workplace. To decrease ETS exposure, efforts to restrict public smoking have proliferated over the past decades. These restrictions have emanated from government as well as voluntary measures by various private industries. Ban on public smoking are effective in reducing non-smokers' exposure to ETS. Workplace smoking bans also influence the intensity of smoking among employees and may increase quit smoking rates. In addition to the health benefits from smoke-free workplaces, there are likely cost savings to employers who implement such policies.

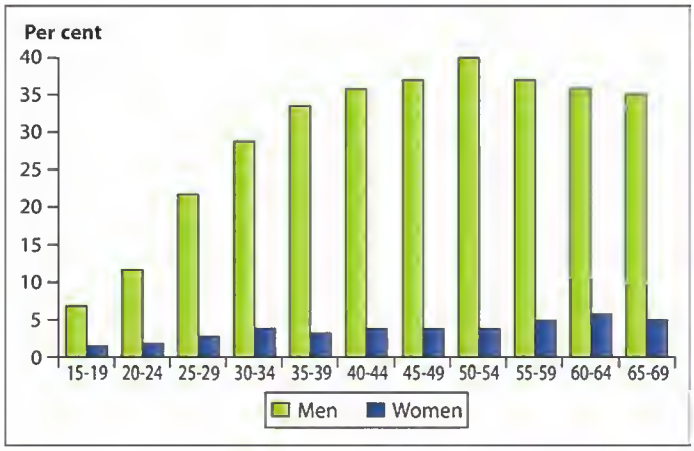

Figure 2: Age-specific prevalence of smoking among men and women in India *(Nationol Fomily Health Survey-2).*

ETS is also an indoor pollutant. Increases in prevalence of respiratory illnesses and reduced level of pulmonary function, measured by simple spirometry, are found in children of smoking parents. Recent meta-analyses for lung cancer and cardiopulmonary diseases, combining data from the best of ETS exposure studies suggest a 25% increase in relative risk.

OCCUPATIONAL INORGANIC AND ORGANIC DUSTS

Table 2 shows the broad categories of chemical and biological substances that are related to occupations and can lead to

Table 2: Occupational Exposure to Inorganic and Organic Dusts and Pulmonary Disease

Occupational Exposures	Respiratory Diseases
Inorganic dusts	
Asbestos: Mining and processing	Asbestos related fibrosis, pleural disease, cancer, mesothelioma
Silica: Mining, stone cutting, sandblasting, quarrying	Fibrosis (silicosis), progressive massive fibrosis, cancer, silicotuberculosis, COPD
Coal: Mining	Fibrosis (coal workers pneumoconiosis), progressive massive fibrosis, COPD
Beryllium: Processing alloys	Acute pneumonitis, chronic granulomatous disease, cancer
Other metals: Aluminium, chromium, cobalt, nickel, titanium, tungsten	Acute pneumonitis, lung cancer, asthma, etc.
Organic dusts	
Cotton dust: Milling, processing	Byssinosis, chronic bronchitis, COPD
Grain dust: Farmers, milling, bakers	Asthma, chronic bronchitis, COPD
Other agricultural dusts: Fungal spores, vegetable products, insect fragments, animal dander, bird and rodent faeces, endotoxins, microorganisms, pollens	Hypersensitivity pneumonitis, asthma, chronic bronchitis
Wide variety of industrial chemicals and toxins	Bronchitis, emphysema, etc.

pulmonary disease. Multiple agents are responsible for such occupational lung diseases but in India only a few toxins such as asbestos, silica, coal-dust, cotton-dust, grain dust and other toxic chemicals are important.

Asbestosis

One important pulmonary disease is due to asbestos and several different mineral silicates including chrysolite, amosite, and anthophyllite. In addition to workers involved in mining, milling and manufacturing of asbestos, those involved in construction trades are also exposed. Community exposure can result from use of asbestos containing mine or mill-tillings such as landfills, road surface or playground material. In India, asbestos has been used extensively since mid-1900s and it is only recently that it is being replaced by synthetic mineral fibres such as fibreglass or slag wool. The major health effects from exposure to asbestos are pleural and pulmonary fibrosis and cancers of the respiratory tract, pleura and, rarely, peritoneum. Asbestosis is diffuse interstitial fibrosis that is directly related to intensity and duration of exposure. Usually moderate to severe exposure of more than 10 years is required for disease to become manifest and can occur following exposure to any asbestiform fibres. The disease resembles other forms of diffuse interstitial fibrosis with decrease in lung volumes and diffusing capacity. Chest radiographs can be used to detect a number of manifestations of exposure such as parietal pleural plaques. Interstitial disease causes linear opacities in lower lung fields, which then spread to middle and upper zones. High resolution CT scan of lungs shows distinct changes of subpleural curvilinear opacities 5 mm to 10 mm parallel to pleural surface. There is no specific therapy and supportive care is similar to other interstitial lung diseases.

Lung cancer (of all histological types) is the most frequent cancer associated with asbestos exposure. A minimum latency of 15 to 19 years is reported between first exposure and the disease. Use of CT scan for screening high risk individuals is being evaluated. Mesotheliomas are also associated with asbestos exposure. Relatively short asbestos exposures for $\leq$1 to 2 years, occurring up to 40 years in the past, have been associated with development of mesotheliomas. These tumours are generally locally invasive and death usually occurs from local extension. There is no effective therapy.

Silicosis

Free silica or crystalline quartz (SiO_2) is still a major occupational hazard. Main occupational exposures include mining, stone cutting, employment in abrasive industries (stone, clay, glass and cement manufacturing), foundry work, packing of silica flour and quarrying especially granite. The pulmonary fibrosis due to silica often follows a dose-response curve after many years of exposure. Workers heavily exposed through sandblasting in confined spaces may develop acute silicosis in less than one year of exposure. The chest radiograph shows profuse miliary infiltration or consolidation and the characteristic CT scan pattern of crazy-paving is at times observed. The disease may be quite severe and progressive despite discontinuation of exposure. Whole-lung lavage may slow progression. Long-term low-intensity exposure results in small rounded opacities in the upper lobes after 15 to 20 years of exposure. Calcification of hilar nodes may occur and lead to characteristic egg-shell pattern. Less hazardous silicates include kaolin, Fuller's earth, mica, silica gel, soapstone, carbonate dusts and cement dusts. Patients with silicosis are at greater risk of acquiring bacterial infections because silica is toxic to macrophages. Infections with *Mycobacterium tuberculosis*, atypical mycobacteria and fungi are common. Another potential complication is autoimmune connective tissue disorders such as rheumatoid arthritis and scleroderma. It is also a potential lung carcinogen.

Coal-Worker's Pneumoconiosis

In India, coal mining is an important industry and coal-worker's pneumoconiosis is a disease with tremendous social, economic and medical significance. Simple radiographic disease is observed in about 10% of coal miners and in as many as 50% of anthracite miners with more than 20 years work on coal face. The prevalence of disease is lower in bituminous coal workers. With prolonged exposure (15 to 20 years) small rounded radiological opacities develop but are not associated with pulmonary impairment. Much of the symptomatology occurs due to development of chronic bronchitis and COPD and the effects of smoking are additive. Complicated disease manifests

as the appearance of nodules on chest radiograph and can involve the entire lobe. This condition can lead to progressive massive fibrosis and premature mortality. Caplan's syndrome includes seropositive rheumatoid arthritis with characteristic pneumoconiotic nodules.

Byssinosis and Organic Dusts

Some of the specific diseases associated with organic dusts are listed in **Tables 2 and 3**. Often the temporal relationship of exposure to symptoms furnishes the best evidence for the diagnosis. Some diseases common to India include those due to cotton dust (byssinosis), grain dust and moldy hay (Farmers' lung). Byssinosis is due to occupational exposure to cotton, flax or hemp. Exposure occurs throughout the manufacturing process, but is most during blowing, mixing and carding of the fibres. Risk is associated with fibre and endotoxin levels and can be substantially reduced by dust control using cotton hoods, increased ventilation and wetting procedures. It is characterised clinically by chest tightness on the first day of the work-week (Monday chest tightness) which becomes less over the week. In 10% to 25% of workers the disease may be progressive, with chest tightness persisting the whole week. After >10 years of exposure persons with recurrent symptoms develop obstructive lung disease.

Grain dust exposure is common in India, but the exact data of illnesses due to this exposure are not available. The presence of obstructive airways disease in grain dust workers is similar to smokers with persistent cough, dyspnoea and wheeze. Farmer's lung is due to exposure to moldy hay containing spores of thermophilic actinomycetes. In UK, the disease occurs in 10 to 50 per 1000 farmers; reliable data are not available in India. Acute Farmer's lung presents as fever, chills, malaise, cough and dyspnoea without wheezing, 4 to 8 hours after exposure and is diagnosed by history of exposure. In chronic disease, there is history of repeated attacks after exposure and patchy fibrosis can occur in lungs. For those patients who present with hypersensitivity pneumonitis, a careful inquiry about occupation, hobbies or other home environmental exposures is necessary to uncover the source of aetiological agent.

OCCUPATION-RELATED HYPERSENSITIVITY PNEUMONITIS

These conditions are also known as extrinsic allergic alveolitis and are due to inflammation of alveoli and terminal airways in susceptible hosts by repeated inhalation of a variety of organic agents (**Table 3**). Causes of hypersensitivity pneumonitides are typically designated by colourful names denoting occupational risk associated with the disease. The frequency of these conditions varies with the environmental exposure and the specific antigen involved. The diseases are immune-complex mediated reaction and cell-mediated hypersensitivity is important. The early reaction is characterised by infiltration of polymorphs in alveoli and small airways and T-cell mediated mononuclear cell infiltration leading to granuloma formation occurring later. The clinical picture is that of an interstitial pneumonitis which varies from patient to patient. The presentation can be acute, subacute or chronic and at times the diagnosis may be difficult. These conditions need to be differentiated from collagen vascular diseases, drug-induced lung diseases and sarcoidosis.

Table 3: Examples of Occupational Exposure-Related Hypersensitivity Pneumonitis

Disease and Occupational Exposures	Antigen and Source
Bagassosis	Thermophilic actinomycetes; sugarcane
Bird fancier's lung	Parakeet, pigeon, chicken, turkey proteins; avian droppings or feathers
Cephalosporium pneumonitis	Contaminated sewage; *Cephalosporium*
Cheese washers' lung	*Penicillium casei;* moldy cheese
Chemical workers' lung	Isocyanates; polyurethane foam, varnishes, lacquer
Compost lung	Aspergillus; compost
Detergent workers' lung	*Bacillus subtilis* enzymes; detergent
Farmers' lung	Thermophilic actinomycetes; moldy hay, grain, silage
Furriers' lung	Animal fur dust; animal pelts
Humidifier or air-conditioner's lung (ventilation pneumonitis)	*Aureobasidium pullulans*, *Candida albicans*, Thermophilic actinomycetes, mycobacterium spp, etc. Contaminated water in humidification or air-conditioning systems
Malt workers' lung	*Aspergillus fumigatus* or *A. clavatus;* moldy barley
Miller's lung	*Sitophilus granarius;* infested wheat flour
Miscellaneous medications	Amiodarone, bleomycin, efavirenz, gemcitabine, hydralazine, hydroxyurea, isoniazid, methotrexate, paclitaxel, penicillin, procarbazine, propranolol, riluzole, sirolimus, sulphasalazine
Mushroom workers' lung	Thermophilic actinomycetes; mushroom compost
Potato riddlers' lung	Thermophilic actinomycetes; moldy hay around potatoes
Streptomyces albus lung	*Streptomyces albus;* contaminated fertiliser
Suberosis	*Penicilium gabratum*; cork dust
Thatched roof disease	*Saccharomonospora viridis;* dried grasses and leaves
Tobacco workers' disease	Aspergillus spp; mold on tobacco
Winegrower's lung	*Botrytis cinerea;* mold on grapes
Woodworker's lung	Wood dust, Alternaria; oak, cedar, pine and mahogany dusts

CLINICAL FEATURES

The exact magnitude of the problem is unknown but there is no question that large numbers of individuals are at risk for developing serious respiratory disease as a result of environmental and occupational exposures. For example, for populations over age 15, 15% to 20% of the burden of asthma and COPD is estimated to be due to occupational factors in USA. In India, the burden may be greater given the high level of exposure. The patient's history is of paramount importance in assessment. Detailed inquiry into specific work practices is required and temporal association of exposure at work and symptoms provides clues to occupation-related diseases.

History provides of exposure to potentially toxic agents at home, hobbies, exposure to second hand smoke, and proximity to traffic and industrial facilities should be obtained. The physical examination of patients with suspected environmental lung diseases may help to differentiate the nature and severity of the pulmonary condition. Unfortunately, these findings do not point to the specific causative agent and other information must be used to arrive at the aetiological diagnosis. The investigations include pulmonary function testing and chest imaging. Measurement of exposure is included if reliable environmental data are available.

Many mineral dusts produce characteristic alterations in the mechanics of breathing and lung volumes that indicate a restrictive pattern. Exposure to organic dusts or chemical agents may result in occupational asthma or COPD. Measurement of FEV_1 before and after a working shift can be used to detect a bronchoconstrictive or acute inflammatory response.

Chest radiograph is useful for detecting and monitoring the response to mineral dusts, certain metals and organic dusts which are capable of inducing hypersensitivity response. The International Labour Organization International Classification of Radiographs of pneumoconiosis classifies chest radiographs according to the nature and size of opacities and extent of pulmonary involvement on a 12-point scale. Small rounded opacities are seen in silicosis and coal-worker's pneumoconiosis and linear opacities in asbestosis. Chest radiograph is insufficient to diagnose extent of the disease in a given patient and CT scan of the chest (regular and high resolution) has improved the sensitivity of identification of diffuse parenchymal abnormalities. Other procedures that may be of use are identification of heavy metals in urine; skin prick testing or specific IgE antibody titres for evidence of immediate hypersensitivity; specific IgG precipitating antibodies for agents causing hypersensitivity pneumonitis; or assays of specific cell-mediated immune responses. Sometimes, a bronchoscopy to obtain bronchoalveolar lavage fluid and transbronchial biopsy of lung tissue may be required for histological diagnosis and differentiation from specific forms of lung diseases and infections. Rarely, video-assisted thoracoscopic surgery to obtain a larger sample of lung tissue may be required for specific diagnosis.

CONCLUSION

Environmental health issues, especially lung diseases, are a major cause of disability and death in India. Despite a large number of legal provisions, the numbers are enormous and it has been estimated by the International Labour Organization that more than 400,000 people die every year due to work related problems including accidents, injuries and chronic diseases. Management of these diseases is currently limited to the prevention and treatment of symptoms and pulmonary manifestations. Increased awareness of the disease conditions, adequate preventive measures and timely interventions are critical to control these diseases.

27.5 Drowning, Near-Drowning and Submersion Injury

Yudh Dev Singh

INTRODUCTION

Drowning is defined as a process resulting from suffocation by submersion/immersion in a liquid, usually water. Near drowning is defined as survival of the victim, at least temporarily, after suffocation by submersion in water. Drowning accounts for nearly 150,000 deaths annually worldwide, including approximately 6,000 fatalities in the United States of America. Near drowning events are estimated to occur many times more than reported drowning deaths. There are approximately 2 million survivors after a drowning event, annually, worldwide. Drowning remains one of the common causes of accidental death worldwide and continues to be associated with high morbidity and mortality.

The American Heart Association in its resuscitation guidelines suggests, that the term 'drowning' should refer to a mortal submersion event in which the victim dies within 24 hours, while the term 'submersion injury' should be used till the time of drowning-related death. In this classification scheme, the term 'near-drowning' has been abandoned.

A swimmer may fall victim to drowning because of over-exertion, exhaustion, panic, inability to cope with swift water current or effects of cold water.

DROWNING PROCESS

The process of drowning is a continuous process which starts with the victim's airway being below the surface of the liquid with breath held voluntarily. This is then usually followed by laryngospasm which is involuntary and secondary to the presence of liquid in the oropharynx. The victim is unable to breathe air during this period, leading to hypercarbia, hypoxia and acidosis due to carbon dioxide retention and oxygen depletion. During this period, the victim frequently swallows large quantities of water. Respiratory movements may become very active but no gas exchange takes place due to obstruction at the level of the larynx. As arterial oxygen tension drops further, laryngospasm abates, and the victim actively inhales varying amount of liquid. Depending on the composition and volume of the liquid aspirated and duration of submersion, changes occur in the lungs, body fluids, blood-gas tensions, acid-base balance and electrolyte concentrations. Surfactant washout, pulmonary hypertension, and shunting, all contribute to the occurrence of hypoxaemia. Water at 10°C or less has marked cardiovascular effects, including increased blood pressure and ectopic tachydysrhythmias.

A victim can be rescued at any time during this drowning process and the chain of events may be interrupted. In absence of effective resuscitative measures multiple organ dysfunction and death usually occurs, mainly due to tissue hypoxia. Post-hypoxic encephalopathy is the most common cause of death in hospitalised victims who have suffered from the drowning process.

PATHOPHYSIOLOGY

Principal physiologic consequence of immersion injury is prolonged hypoxaemia. After initial gasping, and possible aspiration, immersion stimulates hyperventilation, followed by voluntary cessation of breathing and a variable degree and duration of laryngospasm. This further leads to hypoxaemia. Depending upon the degree of hypoxaemia and resultant acidosis, the patient may develop cardiac arrest and cerebral ischaemia. Prolonged asphyxia leads to relaxation of the airway, which permits the lungs to fill with water in many victims ('wet drowning').

Most swimmers initially hyperventilate so as to prolong the duration of underwater swimming. By this procedure, they reduce the arterial partial pressure of carbon dioxide ($PaCO_2$). As the individual swims, oxygen is consumed, partial pressure of oxygen (PaO_2) falls to the levels of 30 to 40 mm Hg, but $PaCO_2$ does not rise sufficiently in time to trigger the urge to breathe. This situation may lead to cerebral hypoxia and loss of consciousness, resulting in drowning.

Lungs are the target organ of submersion injury. Other systems get affected secondary to hypoxia and ischaemic acidosis. Fluid aspirated into the lungs produces pulmonary vasoconstriction and hypertension which is mediated through the vagal stimulation. Based on available evidence from animal studies, significant pathophysiological differences between fresh-water and salt-water aspiration have been emphasised.

In fresh-water drowning hypoxaemia occurs due to inactivation of pulmonary surfactant, resulting in worsening of lung compliance and atelectasis. Perfusion of poorly ventilated areas of the lung results in intrapulmonary shunting of as much as 75% of blood flow and may lead to ventilation-perfusion mismatch. Aspirated hypotonic fluid rapidly passes from the lungs into the intravascular compartment, leading to volume overload and dilutional effects on serum electrolytes.

Hypoxaemia in hypertonic salt-water drowning is secondary to fluid movement into the alveoli caused by the establishment of an osmotic gradient between the capillary-alveolar membrane leading to massive pulmonary oedema and hypertonic serum.

The difference between salt and fresh-water drowning is more obvious among persons who are dead on arrival than among victims who are brought to the hospital alive. Both, fresh and salt-water, produce an inflammatory reaction in alveolar-capillary membrane leading to an outpouring of plasma-rich fluid into alveoli. Individuals who survive the initial course of near drowning are at risk for development of acute respiratory distress syndrome (ARDS).

Drowning Without Aspiration of Fluid (Dry Drowning)

Dry drowning is a controversial subject as few authorities do not accept this entity, but it has been reported in 10% to 20%

of drowned patients in the medical literature. It is more common in adults and is characterised by little or no fluid in lungs. Death occurs due to profound laryngospasm. Entry of water is prevented by laryngospasm. When spasm relaxes due to terminal asphyxia, outpouring of thick mucus may also prevent entry of water. Associated hypothermia may further aggravate impairment of consciousness and motor activity. Recently, the concept of dry drowning has been challenged and it is felt that presence of fluid in the lungs is must to classify victim as having died due to drowning. Victims found deceased in the water and do not demonstrate any evidence of water aspiration at autopsy should be considered as having probably died of some other cause.

MANAGEMENT

It is important to initiate aggressive basic and advanced cardiac life support measures promptly as success of initial resuscitation and duration of submersion are strong determinants of long-term prognosis.

On-Site Resuscitation

The victim should be removed from the water as soon as possible. Restoration of airway patency, breathing, and circulation must be ensured. Mouth-to-mouth breathing should be attempted at the earliest, if possible, even while the victim is in water. Time should not be wasted in attempting chest compressions while in the water since this has not been shown to be effective instead in unconscious patient the cardio-pulmonary resuscitation should be started immediately by keeping the victim's back over a dry hard surface. Heimlich manoeuvre is not recommended because attempting sub-diaphragmatic pressure may increase the risk of aspiration. Obstruction caused by foreign bodies or debris should be looked for. Victim may have other associated conditions, like seizures, head and neck injuries, and these should be kept in mind while attempting initial resuscitation on site or during transportation to a hospital.

Management in a Hospital

On arrival adequate airway must be ensured. Elective intubation may have to be considered even in the absence of respiratory depression with an intention to protect the airway. Attention should be focused to ensure adequate breathing to achieve satisfactory oxygenation and ventilation. Individuals who have hypoxaemia and unable to maintain adequate saturation with 100% oxygen may benefit from mechanical ventilator support with positive end-expiratory pressure (PEEP) while alert patient may be given a trial of non-invasive ventilation Bi-level/ continuous positive airway pressure (BIPAP/CPAP) before invasive ventilation.

Hypoxaemia and hypercarbia are detrimental to the goal of achieving successful central nervous system (CNS) resuscitation, therefore, pulse oximetry, capnography and blood gases may be monitored. Clinical evaluation of cardiac status and peripheral perfusion must be done to assess haemodynamic status. Severe metabolic acidosis may worsen myocardial function and sodium bicarbonate along with fluids may be required to reverse the abnormality of acidosis. Hypovolaemia correction with isotonic fluids may be necessary but fluids should be used judiciously as these victims have an increased risk for developing cerebral oedema.

Victims may have associated hypothermia and may need to be treated for hypothermia. As thermal conductivity of water is 20 times greater than that of air, hypothermia may occur even in tropical waters with temperature as high as 91°F, if protective clothing is not worn and victim is in water for a long time. It is advisable to remove all wet clothing, wrap the victim in a warm blanket and place in a warm area protected from wind. Re-warming with forced hot air or warm water bath may be tried. Active core re-warming by warm water, intra-gastric irrigation, peritoneal dialysis, haemodialysis and extracorporeal circulation, all utilising a system of warming by perfused fluid, have been advocated. There have been few documented survivals after prolonged cold drowning.

Patients who have nearly drowned are likely to have long intensive care unit stay, predisposing them to nosocomial infections. Despite efforts at minimising barotrauma many patients, who have nearly drowned and who required ventilatory support, may develop ARDS. The management of these victims is similar to other non-submersion injury patients who have ARDS.

Laboratory Diagnostic Studies

Diagnostic studies in an individual who had nearly drowned include serum electrolytes, serum creatinine, blood urea, arterial blood gases (ABG) to evaluate the extent of hypoxaemia, status of ventilation, and acidosis, and haemoglobin levels. Toxicology studies, including alcohol levels, may be considered based on the clinical situation. The clinician should obtain a baseline electrocardiogram to look for any cardiac arrhythmia and to evaluate the QT_c interval. Routine computed tomographic imaging of the head is not necessary at the initial stage unless an associated head injury is suspected based on the victim's neurological status.

Prevention

Epidemiologically, nearly half the number of persons who drown is in their teens and about 35% possess good swimming skills. Various factors contributing to drowning accidents include limited swimming ability, unattended children at water bodies, drugs and alcohol abuse, existing medical problems like epilepsy and risky behaviour in water, especially in rainy season in India where flash floods are not uncommon.

Mandatory lifeguards at swimming pools and beaches, improvement in recreational water bodies safety standard, relevant health education and cardiopulmonary resuscitation training of lay public has potential to reduce the death rate from accidental drowning.

27.6 Electric Shock and Lightning Injury

Naveet Wig, Sourabh Malviya

Electrical and lightening injuries are not very uncommon, nearly always accidental, and generally preventable. These environmental injuries cause aggressive pathological lesions which may result in heavy functional and aesthetic consequences. The treatment of these injuries presents many complex multi-level problems which require a proactive approach and treatment.

ELECTRIC SHOCK

Definition

The passage of electric energy through the human body triggers complex reactions which affect the anatomical, histological, biochemical and structural composition. The tissue damage caused by electric current varies from a transient increase in cell membrane permeability to immediate coagulation necrosis of large volumes of tissue.

Epidemiology

Electric shocks are more frequent in developing and under-developed countries having inefficient electric energy system. Overall electrical burns account for 4% to 6.5% of admissions to burn units. Except Turkey (16%), India is having higher incidence rate (3% to 9%) than USA (3%), China (3% to 5%) and Slovakia (2.7%). In a recent Indian study, the amputation rate due to electrical injuries was found to be 4.5% and mortality rate of 3.7%.

The electrical injuries have bimodal distribution of age with work-related injuries in adults, and accidents in children particularly below 6 years, more due to oral contact. Male to female ratio is approximately 2:1 in childhood, while in adults more than 90% of victims are men.

Pathophysiology

The type and extent of an electrical injury is determined by voltage, current strength, the resistance to flow, the duration of contact with the source, the pathway of flow, and the type of current. In the following section, each is explained briefly.

Voltage (V)

Electrical injuries are typically divided into high-voltage and low-voltage injuries, using 500 V or 1,000 V as the cut-off, but above 40 V is also dangerous .

Voltage is expressed by Ohm's law:

$$V = I \times R$$

where, I is current in amperes, R is resistance in ohms, and V is potential in volts.

Current (I)

It is the amount of energy that flows through an object. A very narrow range exists between the threshold of perception of current (0.2 to 0.4 mA) and let-go current. The level above which a person becomes unable to release the current source because of muscular tetany is a 'let-go current'. The effect of current to the body depends on the intensity and varies from tingling sensation, to let-go-current, skeletal muscle tetany, respiratory muscle paralysis, ventricular fibrillation and asystole.

Resistance (R)

It is the impedance to electrical flow across the gradient and depends on electrolyte and water content of the body tissue. Tissues with higher resistance have a tendency to heat up and coagulate which further increases the resistance. Dry skin has a resistance of approximately 100,000 ohms which further decreases with moisture. Sweating decreases the skin's resistance to 2,500 ohms to 3,000 ohms and by immersion in water to 1,200 ohms to 1,500 ohms. The level of tissue resistance varies with the tissues as shown in **Table 1**.

Table 1: Resistance of Body Tissues

Least	Intermediate	High
Nerves	Dry skin	Tendon
Blood		Fat
Mucous membranes		Bone
Muscle		

Duration of contact

In general, longer the duration of contact with high-voltage current, greater will be the heating and degree of tissue destruction caused by the current.

Type of circuit

Electrical circuits are direct current (DC) or alternating current (AC). Direct current causes single muscle contraction and throws the victim away, while by alternating current victim can grasp current source due to muscle tetany (at 40 Hz to 110 Hz).

Pathway

Amount of heat generated, type of injury and tissue/organ affected is determined by pathway of current. Greatest degree of damage occurs at the current source and contact points over the body.

Mechanisms of Injury

The primary electrical injury is burns. Secondary, blunt trauma results from falls or being thrown from the electrical source.

Types of electrical burns

Electrical burns can be classified into direct or indirect and can be classified into four subgroups. The electrothermal burns are due to direct contact while electric arc, flare and flash injury, are due to indirect injury.

1. *Electrothermal burns:* These are the result of low voltage electric burns with a limited affected area, caused by direct contact with the current source.

2. *Electrical arcs:* It is a current spark formed between two objects of differing potential that are not in contact with each other, usually a highly charged source and a ground. Because the temperature of an electrical arc is approximately 2,500°C to 5,000°C, it causes very deep thermal burns at the point where it contacts the skin.
3. *Flame:* Ignition of clothing causes direct burns from flames.
4. *Flash:* When the current does not actually enters the body, but the heat from a nearby electrical arc or current source splashes over the body causes thermal burns and is called the flash burns.

Clinical Manifestations

Clinical features are according to action of current, its pathway and organ affected in between as described in **Table 2**.

Table 2: Clinical Features according to Organ Involved

Organ/System	Clinical Features
Head/ENT	Facial burn, cataract (delayed), perforated tympanic membrane, cervical spine injuries
Cardiovascular system	Cardiac arrest and sudden death (>1000 volts), arrhythmias, ventricular fibrillation or atrial fibrillation, first or second degree heart block or bundle branch block, myocardial infarction or rupture (rarely), venous/arterial thrombosis
Skin	Variety of burns (superficial, partial or full-thickness), peculiar is 'kissing burn'
Musculoskeletal system	Muscle necrosis, mummification of tissues leading to gangrene, compartment syndrome, fracture and dislocation of long bones, spinal fractures and injuries
Nervous system	Confusion, difficulty with short-term memory and concentration, seizure, loss of consciousness, peripheral nerve damage, weakness and paresthesias of limbs, ascending paralysis, amyotrophic lateral sclerosis, or transverse myelitis (delayed)
Psychiatric	Depression, anxiety, job failure, aggressive behaviour and suicide
Respiratory	Chest wall muscle paralysis, respiratory arrest
Renal	Myoglobinuria, rhabdomyolysis, acute tubular necrosis, acute renal failure
Other systems	Rarely direct liver injury, focal pancreatic and gallbladder necrosis, intestinal perforation and fistula formation, stress ulcers, burn ileus

ENT = Ear, nose and throat.

Complications

- Cardiac arrest leading to hypoxic brain damage
- Renal failure due to myoglobinuria, acute tubular necrosis (ATN)
- Stress ulcers
- Burn infections like clostridial myositis
- Pneumonia
- Sepsis
- Multi-organ dysfunction syndrome (MODS)
- Tissue loss, fractures and amputations
- Delayed neuropsychiatric manifestations

Management

Pre-hospital care

Secure the scene, like power source should be turned off.

Spine immobilisation may be required in case of spinal injury.

Initial resuscitation

Initiate prolonged cardiopulmonary resuscitation (CPR), in case of cardiorespiratory arrest and do proper cardiac monitoring. See Chapter 11, Section 7.

Specific therapy

Rhabdomyolysis: Alkalisation of urine, intravenous fluids, mannitol and furosemide may prevent development of renal failure.

Electrolytes correction, i.e. hyperkalaemia.

Burn and wound care: Proper debridement, escharotomy, antibiotic dressing and prophylactic systemic antibiotics.

Extremity injuries: Early fasciotomy, carpal tunnel release, amputation (extensive damage).

LIGHTENING INJURY

Definition

Lightening injury is caused by a unidirectional, massive, current impulse with several return strokes back to the cloud, which is neither the direct or alternating current, lasting for a very short period, leading to mild superficial burns to various systemic injuries.

The duration of lightening bolt is 1/100 to 1/1,000 of a second, voltage of approximately 1 billion V, currents ranging from 12,000 to 200,000 A and the temperature dissipation of about 30,000 K.

Epidemiology

The incidence is likely to be more common in males of less than 35 years of age, as they indulge in more outdoor activities. Lightening is more common near the equator. Extreme temperatures are generally the most common environmental killers.

Mechanism of Injury

Lightening injury may occur by direct contact or indirect contact with the light stricken object.

Direct contact

Orifice entry: It strucks head and may enter eyes, ears and mouth to flow internally.

Indirect contact

Side flash or splash: Lightening jumps from primary striking object to a nearby person on its ground.

Ground current or step voltage: A difference in electrical potential between person's feet may occur when lightening flows through the ground, current then flows through person rather than the ground.

Blunt trauma: Injury occurs if the person is thrown away by lightening current.

Clinical Manifestations

Lightening injuries causes minor injuries, cardiac arrest and other manifestations as presented in **Table 3**.

Table 3: Features of Lightening Injury

Organ/System	Clinical Features
Head/ENT	Skull fractures and cervical spine injury (blunt trauma), tympanic membrane rupture, disruption of the ossicles and mastoid, CSF otorrhoea, haemotympanum, and permanent deafnesss
Eye	Corneal lesions, uveitis, iridocyclitis, hyphema, vitreous haemorrhage, optic atrophy, retinal detachment, and choroidoretinitis
Cardiovascular system	Cardiac arrest due to asystole, ventricular fibrillation (rare), other dysrhythmias
Skin	Mottling, burns: Linear, punctate, feathering ('Litchenberg Figures'), or thermal burns
Musculoskeletal system	Fracture and dislocation of long bones, spinal fractures and injuries
Nervous system	Keraunoparalysis (transient paralysis), permanent paresis or paraesthesias, anterograde amnesia, peripheral nerve damage, intracranial haemorrhages, seizures, loss of consciousness, delayed muscle atrophy
Psychiatric	Depression, anxiety
Respiratory	Pulmonary contusion and haemorrhages
Other systems	Blunt abdominal injuries

Complications of Lightening

- Cardiac arrest and death
- Iatrogenic complications secondary to over aggressive management
- Hearing loss from tympanic membrane rupture
- Spinal injuries
- Neurologic damage—paraplegia or haemiplegia
- Neuropsychiatric manifestations
- Chronic pain syndromes

Treatment

Pre-hospital care

- Victim and caregiver should guard themselves from another lightening injury.
- Spinal immobilisation.

Hospital care

- Observation only, if minor injuries and superficial burns.
- Immediate aggressive and persistent cardiopulmonary resuscitation in case of cardiac arrest.
- Keraunoparalysis and transient unconsciousness may require observation.
- Consultation for the injuries to ear, eyes and blunt trauma injuries from respective specialists.

Prognosis

Morbidity and mortality are largely affected by the particular type of electrical contact involved. Proper resuscitation with monitoring of limb tissue pressure and wound care can maximise tissue salvage; reduce renal failure, and increased survival of patients with lightening and high-voltage electric injuries.

CONCLUSIONS

Electrical and lightening injuries are environmental injuries causing various anatomical, structural and functional disturbances in the body. Electrical injuries may cause superficial or deep burns and various complex injuries to the organs, burn infections and renal failure. While lightening injury may not cause severe burns but can result in more cardiac and neurological damage. Electrical injuries require more intense management, like burn wound care, aggressive fluids and treatment pertaining to systemic complications than lightening injuries.

27.7 Effects of Extremes of Temperature

Rajvir Bhalwar

INTRODUCTION

The term 'heat stress' or 'cold stress' is applied to any degree of environmental heat or cold that causes physiological thermo-regulatory mechanisms to get activated. Human beings are homoeothermic creatures whose physiology attempts to maintain a constant core body temperature of 37°C (range 36°C to 38°C). Obviously, this requires balancing of the body heat production with heat loss which is achieved by a combination of physiological mechanisms (as peripheral vasodilatation or vasoconstriction, changes in heart rate, sweating or shivering) and behavioural mechanisms (increase or decrease in voluntary physical activity, seeking appropriate shelter, etc). In addition, environmental conditions, viz. temperature, humidity and speed of air also greatly determine whether a person will be subjected to thermal stress. Therefore, prevention and management of thermal stress disorders requires an understanding of these physiological, behavioural and environmental mechanisms and manipulating them appropriately. For the purpose of thermo-regulation, the human body can be conceived of having two 'layers'—an outer periphery or 'shell' consisting of skin, subcutaneous tissue and muscles, and an inner 'core' consisting of brain, heart and viscera.

EPIDEMIOLOGY OF HEAT STROKE

Adverse effects of heat stress are an important cause of morbidity and mortality not only in the developing countries but in the developed countries as well. In India, 3,194 deaths due to heat stroke (HS) have been recorded over the 5-year period 1999 to 2003; the actual magnitude may be much more. The central and northern plains, western deserts and tropical forest areas of north-east have environmental conditions causing heat stress during the months of April to September. The risk is much higher among certain categories (**Table 1**).

Table 1: Persons at High Risk of Heat Stress

Extremes of age (<5 years or >65 years)
Pregnancy
Occupation—workers in military, agricultural, construction and industrial settings, labourers, sports-persons and miners
Low level of physical fitness
Lack of acclimatisation to environmental heat
Obesity
High ambient temperature, high atmospheric humidity, low air velocity
Alcohol use—acute and chronic
Skin diseases—extensive prickly heat, psoriasis, pyoderma
Sleep deprivation
Co-existing febrile illness, renal, thyroid, cardiovascular and metabolic diseases
Previous history of heat-illness
Use of drugs or habit forming substances—phenothiazines, anti-cholinergics, ACE-inhibitors, MAO-inhibitors, cocaine, amphetamines, anti-histamines

ACE = Angiotensin converting enzymes; MAO = Monoamineoxidase.

PATHOPHYSIOLOGY

As a part of thermo-regulatory process, even an increase of 1°C in the temperature of blood generates signals to the hypothalamic thermo-regulatory centre leading to increase in heart rate and cardiac output, which coupled with the sympathetic cutaneous vasodilatation increases the skin blood flow. Sweating is activated and its evaporation cools the body surface, unless the air surrounding the body is fully saturated with water, i.e. having relative humidity (RH) of 100%. Increasing the movement of air in contact with the body also increases cooling by promoting evaporation of sweat. Sweating, however, leads to loss of water and salt, which may be as high as 2 litres per hour under conditions of high humidity and physical exertion. If the water and salt are not replaced adequately and concurrently, the fluid reserves would be depleted, even though the body core temperature may not be very high. This condition is called *'heat exhaustion' (HE)*. However, at times, the thermo-regulatory response may be overwhelmed by the hot environment, even though the fluid and salt reserves of the body may be adequate. Such thermo-regulatory failure, coupled with exaggerated acute phase response (increased production of inflammatory cytokines and endothelium derived vasoactive factors and activation of coagulation process) and alterations in the expression of heat shock proteins (HSPs), leads to *'heat stroke'*. For these reasons, a number of cases of HE, if not properly managed, would also pass on to HS. Following HS, a multiple organ dysfunction syndrome (MODS) results from a complex interplay between the cytotoxic effects of heat and the inflammatory and coagulation responses of the host.

CLINICAL FEATURES OF HEAT STROKE

The classical clinical description of HS is the triad of hyperpyrexia (rectal temperature >40°C), central nervous system (CNS) dysfunction and anhidrosis. Anhidrosis, however, is not a diagnostic requirement since it may appear later when volume depletion is severe. Moreover, in cases which initially start as HE or cases of HS which occur among young people who have been exerting physically, the skin may be moist. Brain dysfunction is usually severe (coma, stupor or delirium), but may sometimes be subtle, manifesting as inappropriate behaviour or impaired judgement. In fact, any person who develops irrational or confused behaviour following exposure to heat stress either with or without a history of physical exertion, should be treated as a potential HS patient. Other clinical features include evidence of dehydration, shock, convulsions and, sometimes, mild icterus. Two forms of HS are recognised, viz. the classical HS (CHS) and the exertional HS (EHS) form. It is important to recognise the clinical differences between the two forms (**Table 2**).

Table 2: Differences Between Classical Heat Stroke and Exertional Heat Stroke (EHS)

Characteristic	CHS	EHS
Age group	Elderly	15 to 45 years
Previous health status	Usually compromised	Healthy
Concurrent activity	Sedentary	Strenuous activity
Habit of drug use	Often present	Usually present
Sweating	Often absent	Frequently severe
Skin	Dry	May be moist
Rhabdomyolysis	Unusual	Excessive

DIFFERENTIAL DIAGNOSIS

Heat stroke should be considered as a possibility in any patient who presents with elevated body temperature and altered mental functions. Important and common diseases which need to be excluded are tropical infectious diseases like cerebral malaria, encephalitis and meningitis. Other diseases which need to be considered are thyroid storm, phaeochromocytoma, status epilepticus, cocaine and amphetamine abuse, delirium tremens and cerebro-vascular accident especially pontine haemorrhage. The diagnosis of HS is usually one of exclusion and the typical history of exposure to hot environment during the immediate past is an indication towards heat stress hyperthermia.

LABORATORY INVESTIGATIONS

Blood should always be drawn for a peripheral blood smear for malarial parasite as well as for other infectious causes of hyperpyrexia with CNS dysfunction. Laboratory findings of HS include haemoconcentration, mild leucocytosis, elevation of blood urea, and in some patients of EHS, hypoglycaemia. Impaired blood coagulation with lowered prothrombin, low platelet counts, hypofibrinogenaemia and features of disseminated intravascular coaglation (DIC) may be seen. Serum electrolyte studies generally show normal or high chlorides, hypokalaemia, hypocalcaemia, and hypophosphataemia. Enzyme studies show increase in creatine phosphokinase (CPK), serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) levels. If rhabdomyolysis or acute renal failure (secondary to acute tubular necrosis) has set in, urine will show myoglobinuria, proteinuria, and hyaline and granular casts, and there will be an increase in blood uria nitrogen (BUN) levels.

Complications

The most serious complication of HS is MODS, manifesting as hepatic failure, renal failure, cerebellar damage, cerebral oedema and arrhythmias. Rhabdomyolysis and DIC are other serious complications.

PROGNOSIS

HS must be treated as an emergency. Mortality may be as high as 30% to 50% among cases where treatment is delayed. Mortality is directly proportional to the level of core temperature and its duration. Prolonged coma of more than 2 hours is a poor prognostic indicator. Among survivors, neurological recovery generally occurs but some deficit may persist in up to 20% of the cases. Survivors of HS, who have suffered for hyperpyrexia for a few hours may get permanent brain damage.

TREATMENT

HS must be treated as a serious medical emergency. Delay in institution of appropriate therapy by even few minutes may make all the difference between life and death. The treatment objectives are: firstly, rapid cooling to bring down the core temperature to below 39°C and reducing it by approximately 0.2°C per minute; secondly, rehydration and care of comatose patient; and, thirdly, to support the organ system function. Cooling measures should be stopped once core temperature falls below 39°C. The steps in the management of HS at two different levels (first aid level, primary care/solo physician level and hospital level) are shown in **Tables 3 and 4**, respectively.

Table 3: Management at First Aid Level

Record rectal temperature. If it is not possible to record rectal temperature, record oral temperature and add 0.5°C
Try and move patient to a cooler and shaded place
Remove the clothes
Spray skin with water at 25°C to 30°C or wrap the patient with a sheet soaked in water at 25°C to 30°C
Continue fanning manually or with an electrical fan
Keep vigorously massaging the skin to prevent cutaneous vasoconstriction during cooling
If available, place ice packs or towel soaked in cold water around the neck, axillae and groin
Nurse in the comatose position; clear oral secretions
Transport to the medical facility as an emergency

Table 4: Management at the Hospital (Secondary/Tertiary Care Level)

Continue cooling measures
Start monitoring core temperature with a thermometer calibrated to measure high temperature (40°C to 47°C)
In case temperature is not reducing, immerse the patient in tub containing cold or iced water, keep the head and neck outside the water surface
In case patient is shivering, give intravenous (IV) chlorpromazine 25 mg to 50 mg
Intubate the patient, establish ventilatory support, give oxygen inhalations
Continue IV fluids; maintain mean arterial pressure at 60 mm Hg; if required, consider administering a vasopressor
Frequently monitor blood electrolytes to guide the IV fluid therapy
In case there is evidence of shock, cerebral oedema or adrenal insufficiency, administer IV hydrocortisone hemisuccinate 100 mg or betamethasone 4 mg to 8 mg
If facilities exist, give a cold gastric lavage after intubating the patient
Antipyretics do not seem to have any role. There are reports about efficacy of dantrolene sodium but the same have not been proven by clinical trials
If there is evidence of rhabdomyolysis or acute renal failure, give IV normal saline, furosemide 40 mg, mannitol 0.25 g/Kg body weight and 250 ml of 4% IV sodium bicarbonate. Heparinisation may be required if there is evidence of DIC
Advice bed rest for about 7 days after recovery from heat stroke since temperature control mechanisms may remain labile after recovery

Heat Exhaustion

The features which differentiate HE from HS are that core temperature is less than 40°C and there is no evidence of CNS dysfunction, though some patients may be anxious or irritable. The salient differentiating features between HS and HE are given in **Table 5**.

PREVENTION OF ADVERSE EFFECTS OF HOT ENVIRONMENT

1. Avoid exposure to outside environment during summer, from 10 am to 5 pm, unless necessary.
2. Keep drinking water regularly, especially if exerting. Drink 250 to 300 ml water every half an hour even if not thirsty. Drink 5 to 6 litres cool water in a day. Carry a bottle of cool drinking water. Remember that thirst is not a good indicator of dehydration, and hence, one should not wait for thirst to develop before starting to drink fluids.
3. Put light coloured, loose and permeable clothes (as cotton) in 1 to 2 layers only.
4. Put on wide brimmed hat of light colour when going out.
5. Keep children <5 years or elderly >65 years away from sun as far as possible. Never leave them in closed, parked cars in hot weather.
6. Apply a sun screen ointment of sun protection factor of at least 15 when going out in sun.
7. Avoid alcohol, cocaine and other habit forming drugs.
8. Acclimatise to heat by undertaking gradually increasing intensity of physical exertion in gradually increasing hot environment, for 80 to 100 minutes daily for 10 to 14 days.
9. If feeling exhausted, too thirsty, confused or running out of memory/consciousness, move to a cool, shaded place, sit or lie down, drink cool water and seek help.

Table 5: Salient Differentiating Features Between Heat Stroke (HS) and Heat Exhaustion (HE)

Aspect	HS	HE
Cause	Inadequacy or failure of heat loss mechanisms	Excessive fluid loss leading to hypovolaemia
Warning signs	Headache, weakness, loss of consciousness	Gradual weakness, excessive sweating, anxiety, nausea, syncope
Manifestations	Hot, dry skin with little sweating; full, bounding and rapid pulse, very high temperature (usually >40°C)	Pale, greyish, clammy skin; weak, slow pulse; low blood pressure; temperature moderately raised (usually <40°C)
Management	Emergency cooling by wrapping or immersion in cool water, ice packs over head, axillae and groin; immediate evacuation to hospital	Patient placed recumbent with feet elevated; oral replacement of water and salt rarely intravenously)

OTHER ADVERSE EFFECTS OF HOT ENVIRONMENT

Heat Cramps

These manifest as spasms of muscles, especially lower extremity and shoulder, following heavy muscular exertion in hot environment, with associated intake of hypotonic oral fluids. Treatment consists of oral administration of 0.1% to 0.2% salt solution. Severe cases or those with vomiting should be given intravenous normal saline.

Heat Tetany

Symptoms include carpopedal spasms and paraesthesiae following short exposures to excessively hot environment, leading to hyperventilation and respiratory alkalosis. Treatment consists of removing the patient to a cool environment and asking him to slow down the respiration.

Heat Syncope

This manifests as syncope following exposure to heat stress as a result of peripheral vasodilatation. One should exclude other serious causes of syncope. Treatment consists of removal of patient to a cool environment and oral rehydration.

Heat Oedema

This presents with pitting oedema of hands and feet, usually in the elderly, following exposure to heat stress. Other causes of oedema should be excluded. Treatment consists of reassurance, elevation of affected limbs and, if required, compression bandage.

Prickly Heat *(Lichen Tropicus, Miliaria Rubra)*

It manifests as erythematous, pruritic, maculopapular rash. If the condition is allowed to progress, extensive prickly heat that can progress to chronic dermatitis and superinfection can occur. Prevention consists of regular baths with cool water after gently scrubbing the skin, and wearing loose, light weight clothing. Local application of calamine lotion or chlorhexidine lotion alongwith oral antihistamines is helpful. In case of severe forms, local application of 1% salicylic acid cream and antibiotics for superinfection (usually *Streptococcus aureus*) should be given.

ADVERSE EFFECTS OF COLD ENVIRONMENT

Cold stress leads to adverse effects which can be generalised (hypothermia) or local cold injuries which may be further classified as of freezing type (Frost Nip, Frost Bite) or non-freezing type (Chilblains, Trench foot, Raynaud's phenomena).

EPIDEMIOLOGY OF COLD STRESS

Extreme cold conditions occur in India in the Himalayan, Sub-Himalayan and the North Indian plains with cold waves and deaths being recorded every year. Over the 5-year period 1999 to 2003, a total of 3,524 deaths due to cold exposure have been reported; the actual magnitude may be higher. Groups at particularly high risk include military personnel, agriculturists, mountaineers and persons engaging in adventure or winter sports. From socioeconomic aspect, persons with low income, poor housing and inadequate clothing are at particularly high risk especially during the cold wave conditions. Extremes of age

(<5 years or >65 years), physical exhaustion, pre-existent malnutrition or starvation, use of alcohol, substance abuse, dehydration, and underlying diseases (hypothyroidism, hypoadrenalism, diabetes and cardiovascular disease) increase the risk of cold stress. From environmental point of view, besides low atmospheric temperature, the adverse effect is greatly accentuated if wind is blowing at a fast speed (wind chill factor) or if concomitant rain or snowing is present. Immersion/submersion in cold water bodies, as may occur when a boat overturns during winter months, also carries a risk of hypothermia, besides drowning.

PATHOPHYSIOLOGY

The physiological protective responses to generalised cold involve, first, peripheral vasoconstriction which tends to act as an "insulator" for the inner body core in an effort not to lose the core heat, and secondly, increased thermogenesis by shivering. Coupled with behavioural factors as seeking shelter, putting on clothes and increased muscular activity, the body physiology tries to normalise the core temperature. In the initial stages, there is an increase in metabolism, heart rate and cardiac output. However, as exposure to cold increases, the overall metabolism slows and there is reduction in heart rate, cardiac output and respiratory rate.

Local cold induced injuries are due to formation of 'ice-crystals' within the cells followed by rupture of cells due to endosmosis or due to tearing by ice-crystals. Distal areas of the body and areas with high surface-to-volume ratio (ears, fingers, toes, nails and cheeks) are more susceptible.

CLINICAL FEATURES OF GENERALISED HYPOTHERMIA

Early symptoms of generalised adverse effects of cold become apparent as the 'core' (rectal) temperature drops below 36°C and are clearly evident once it is below 35°C. Depending on the core temperature, hypothermia may be classified as borderline (36°C to 35°C), mild (35°C to 32°C), moderate (32°C to 28°C) and severe (<28°C). One of the earliest symptoms of hypothermia is a change in behaviour, but unfortunately, the victim is the last person to notice such changes himself. There are mild mood changes, lack of affect, apathy, uncoordinated movements, ataxia, confusion and decreased ability to sense cold. Initially, there is tachycardia, tachypnoea and shivering which can be voluntarily controlled. However, as hypothermia becomes more severe, (32°C to 35°C) there is bradycardia and decrease in respiratory rate. Higher reasoning becomes impaired (e.g. the person may not be able to count backwards from 100, subtracting 9 every time). Shivering becomes violent and cannot be stopped voluntarily. Lack of appreciation of cold may lead to 'paradoxical undressing' (the person starts removing the clothes rather than putting on more clothes). Gait becomes stuporous. As the core temperature falls below 32°C, shivering stops. Skin becomes blue and puffy. Patient becomes semiconscious and muscles start becoming rigid. Trismus is often present. There is marked bradycardia and lowering of respiratory rate. Electrocardiogram (ECG) shows the 'J' (Osborn) wave at the junction of QRS complex with ST segment in about 80% cases and this may be confused with myocardial ischaemia. Cardiac dysrythmias are very common, especially atrial/ventricular fibrillation. There is lowering of arterial partial oxygen tension, and often increases in serum aspartate aminotransferase, creatine kinase and serum amylase. If the cause of hypothermia is not immediately identifiable, then investigations directed towards thyroid and pituitary dysfunction, hypoglycaemia and drug intoxication should be undertaken. Once the core temperature drops to 28°C or less, the patient is completely unconscious with severe bradycardia. Radial pulse may not be palpable and carotid pulse may reveal as low as 2 to 3 beats per minute. Respiratory rate is also reduced to 1 to 2 per min. Muscles become rigid and pupils dilated. At this stage the patient may appear dead but may not be so. Carotid pulse must be carefully palpated in all such cases.

INVESTIGATIONS

The most important investigation in a patient of hypothermia is to accurately monitor the core temperature. If possible, a radiograph of the chest or other regions may be taken, primarily to rule out other traumatic injuries since coexisting traumas, haemorrhage and shock may worsen the manifestations of hypothermia. Blood biochemistry usually shows metabolic acidosis, azotaemia and haemoconcentration. ECG may show the 'J' wave as described above, bradycardia and dysrhythmias.

Treatment

Hypothermia should be treated as a medical emergency. Early recognition and institution of therapy may make all the difference between life and death. The basic principle of management is quick warming of the 'core' without causing simultaneous vasodilatation of the periphery, from the level of first aid till the most elaborately equipped critical care facility. The steps in management at three different levels (first aid level, primary care/solo physician level and hospital level) are shown in **Tables 6 and 7**, respectively. During the process of re-warming, one should be very careful as regards the phenomena of 'after-drop'. This happens if the extremities are also rewarmed or else the patient starts exerting again, leading to vasodilatation of peripheral vessels in arms and legs, thus releasing extremely cold blood as well as acidic metabolites (which were trapped in this part of the vasculature). Once this cold blood and metabolites are shunted back, it further cools the brain, heart and viscera as well as making the myocardium more susceptible to dysrhythmias. Hence, during re-warming, do not warm the extremities and do not let the patient exert even if consciousness has been regained.

One also needs to be careful while instituting cardiopulmonary resuscitation (CPR) in a patient of hypothermia, who may appear dead with dilated, fixed pupils and no discernible pulse or respiration. Such patient may be still alive, in a 'metabolic icebox'. Instituting CPR in such a patient may precipitate an 'after drop' and dangerous dysrhythmias. Hence, in such patients, one should carefully check the carotid pulsation and respiration to detect very low heart rate (2 to 4 per minute) and low respiratory rate (2 to 3 per minute). If there is evidence of life, one should start re-warming and not institute CPR. CPR should be started only if it is confirmed that pulse is absent. Once the pulse started, CPR should be continued as the patient is being rewarmed. There have been cases when patients with severe hypothermia

Table 6: Management at First-Aid Level

Remove wet clothing only when patient has reached a warm, dry and sheltered environment and not in the open
Immediately wrap the patient all around, including head, with warm clothes, blankets, quilts, sleeping bags whatever insulatory material is available, even newspapers or rags. Make an 'insulatory wrap' of about 4 inches thickness all around the patient. Provide a wind and waterproof outer most layer, as polythene sheets
Make hot packs with warm water bottles covered with a cloth, or warm pads, at 42°C to 45°C, and apply them to axillae, groin and neck
Do not warm the extremities at this juncture. Place arms and hands on the sides and not on the abdomen or in axillae
Do not let patient do any physical activity. Treat as a 'stretcher case'
If patient can take orally give warm, sweetend tea or milk to provide 'fuel'
Do not massage the limbs
Do not give alcohol or tobacco
Evacuate to a sheltered place preferably to a medical facility at the earliest

Table 7: Management at Hospital Level

Nurse in warm room, preferably in an ICU
Measure rectal temperature and other vital parameters
Recheck intravenous line. Draw blood for investigations
Continue 5% dextrose warmed to 37°C to 41°C. Change the fluid depending on laboratory results
Undertake endotracheal intubation (unless patient is alert and possesses intact airway reflexes). If trismus is present then blind nasotracheal tube is the only practical non-surgical option
Give warm humidified oxygen at 42°C to 45°C, 4 litres/min through endotracheal tube or facemask
Monitor cardiac rhythm and blood gases, including pH

have been given CPR for as long as 3 hours and finally revived. The patient should be declared dead only after he has been re-warmed to core temperature of 36°C and CPR fails at that temperature. The dictum is *A patient of hypothermia, in finality, is never 'cold and dead' but is 'warm and dead'*.

Accidental Hypothermia Among Elderly

Elderly persons (age >65 years) are particularly prone to develop hypothermia, especially in winter season. The age-related autonomic defects, leading to low peripheral resting-blood-flow, a non-constrictive vasomotor response to cold and easily provoked orthostatic hypotension are all aetiologic factors in this increasesd susceptibility, which may be compounded if there is concomitant phenothiazine usage, endocrine disorders, poor nutritional status and pulmonary infection. The exposure need not be to severe cold, since in elderly, hypothermia may be precipitated on exposure to even mild environment with ambient air temperatures of 15°C to 18°C. Hypothermia develops insidiously, over many hours to a few days. Therefore, health care providers should be alert for recording even lowered body temperatures among elderly, since generally in clinical practice, only higher temperatures (and not lowered temperatures) tend to be recorded. Treatment consists of *gradual* (and not rapid) re-warming by moving to a warm room and warming with blankets (**Table 7**).

LOCALISED ADVERSE EFFECTS OF COLD

Frost Nip and Frost Bite

Frost nip involves freezing of top layers of skin tissue. It is generally reversible and manifests as numbness and white, waxy or rubbery feeling of the affected skin but the deeper tissue is still soft. Frost bite is the more severe form and affects all layers of the skin and often the deeper tissues also. Frost bite is of four degrees, depending on the depth of the tissue involved. As an urgent first aid measure, remove any constrictive clothing or bands. Start local warming by placing the affected part in a warm water bath at 40°C to 42°C. If nothing is available, place the affected part in the axiliae or on the stomach of another healthy person. Analgesics and sedatives should be given for relief of pain. Initiate immunisation with tetanus toxoid and evacuate to a surgical facility at the earliest opportunity. If generalised hypothermia and local frost bite both are present, first treat the patient for generalised hypothermia. Local re-warming for frost bite should be undertaken only after core temperature has returned to normal.

Non-Freezing Cold Injuries

These include chilblains and trench (immersion) foot, occurring due to prolonged exposure to cold environment with wet conditions. Chilblains manifest with initial pallor of affected area (usually fingers, toes, cheeks or earlobes) followed by erythema, pruritus and intense pain. Prevention by way of avoidance of exposure to cold and wet conditions among susceptible persons is the most important. Otherwise, there is no specific treatment, though symptoms may be ameliorated by oral nifedipine in some cases.

Trench foot is caused by prolonged exposure of feet to cold and wet conditions. The skin is reddened with tingling pain and itching. Gradually, the skin becomes pale, mottled and finally dark purple, grey or blue. If the circulation remains impaired for more than a few hours, permanent damage to the affected part can occur. Treatment consists of gentle drying, elevation of the affected limb and keeping it at an environmental temperature of 18°C to 22°C while keeping rest of the body warm. NSAIDS may be given for relief of pain. The patient should not walk on the affected limb till fully cured. Prevention is, once again, very important and consists of keeping the feet clean and dry, dabbing the feet with aluminium hydroxide powder thrice daily, and changing into dry socks and shoes at the earliest.

PREVENTION OF ADVERSE EFFECTS OF COLD

1. Dress properly for cold weather. The basic principle for dressing for cold climate is to dress in many layers. The innermost layer should be of polypropylene with numerous air pockets, to serve as 'vapour transmission layer'. The middle layer should be 3 to 4 layers of woolen garments, which serves as the 'insulatory layer' by trapping the air. The outer most layers should be of non-permeable or semi-permeable material made of a wind and water resistant material. In addition, the clothing should be clean and dry.

2. Protect the head very well with a woolen cap, since almost 30% of the body heat is lost through the head.
3. Protection of the head, fingers and feet is extremely important, with proper woollen caps, gloves, socks and shoes.
4. As far as possible do not overheat the body by way of physical activity to the extent that it leads to excessive sweating and dampens the clothes. If clothing becomes wet, change into dry clothing at the earliest possible.
5. Insulate metallic objects which are likely to come in contact with the body and with woolen material.
6. Give special attention to children <5 years, elderly >65 years, and those with poor nutritional status or with diseases of thyroid, adrenal cortex or cardiovascular system.
7. Maintain good nutritional status and adequate hydration with frequent warm, calorie containing drinks.
8. Do not use alcohol, especially if going out in the cold. Avoid tobacco use.
9. Be on the watch-out for earliest symptoms of generalised effects (intense shivering and mental changes) or local effects (skin colour changes, blistering or loss of sensation) and institute urgent first aid.

27.8 High Altitude Medicine

Anuj Chawla

INTRODUCTION

An estimated 140 million people permanently live at altitudes greater than 2,500 m. In addition, thousands travel to high altitude areas each year either for work or as tourists for leisure and adventure.

Definition

High altitude (HA) has been defined as an altitude greater than 2,500 m to 2,700 m above mean sea level. An altitude of 2,700 m is a more physiological definition of HA since it results in an alveolar partial pressure of oxygen (P_AO_2) of 60 mm Hg, at which the effects of hypoxia are easily recognisable. Altitudes greater than 5,800 m are classified as extreme altitude (EA). HA poses a number of environmental challenges (**Table 1**), the most important being hypobaric hypoxia. This requires complex physiological adjustments by the body to ensure normal function. These physiological adjustments constitute 'altitude acclimatisation'.

Table 1: Major Environmental Challenges at High Altitude

Hypobaric hypoxia: Barometric pressure reduces with altitude thereby causing a reduction in the partial pressure of oxygen in ambient, inspired and alveolar air.
Low environmental temperature: The environmental temperature falls by 1°C per 150 m gain in altitude. High wind velocity at HA adds to the low temperature due to a 'wind chill factor'.
Low absolute humidity in the atmosphere: This increases the insensible water loss from the body and predisposes to dehydration.
Increased solar and ionizing radiation: Ultraviolet radiation increases by 4% with every 300 m gain in altitude and can cause harmful effects, especially in the eye and skin.

Acclimatisation to High Altitude

The earliest and most important manifestation of altitude acclimatisation is hyperventilation. This results in respiratory alkalosis, which is corrected by renal excretion of bicarbonate over 2 to 3 days. A relatively slower physiological adjustment is an increase in haematocrit, which requires weeks to develop. The hyperventilation and raised haematocrit try to correct tissue hypoxia. Other important physiological changes include raised pulmonary artery pressure (PAP) due to hypoxic pulmonary vasoconstriction, elevated sympathetic activity, increased capillary density and alteration in metabolic enzymes for optimal cellular function in a hypoxic environment. The human body is unable to acclimatise successfully at EA. A failure of or impaired acclimatisation can result in high altitude illnesses.

High Altitude Illnesses

It refers to clinical syndromes that can affect un-acclimatised individuals at HA. It commonly includes the cerebral syndromes of acute mountain sickness (AMS) and high altitude cerebral oedema (HACE) and the pulmonary syndrome of high altitude pulmonary oedema (HAPE). HA illnesses are classified based on their time of onset (**Table 2**). Acute illnesses occur within hours to days of ascent to HA, sub-acute within weeks to months and chronic, after years of stay at HA. A number of factors determine the occurrence of HA illnesses (**Table 3**).

Table 2: Classification of High Altitude Illnesses

Acute

ACUTE HIGH ALTITUDE ILLNESSES

Acute Mountain Sickness (AMS)

Definition and epidemiology

AMS is a syndrome of non-specific symptoms and is defined as the occurrence of headache along with the presence of one or more of gastrointestinal symptoms, insomnia, dizziness, lassitude or fatigue in an un-acclimatised individual who has recently arrived at HA. The incidence of AMS varies with the altitude and rapidity of ascent and ranges from 3.1% at 2,000 m to 53% at 5,000 m.

Aetiopathogenesis

The critical factor in the pathogenesis of AMS is hypoxaemia and AMS may represent the benign end of a clinical spectrum with the malignant end being HACE. However, evidence of

cerebral oedema and raised intracranial tension in AMS is inconsistent. Other pathophysiological mechanisms may include hypoxia-mediated release of vasogenic substances, activation of the trigeminovascular system, and free radical-mediated alteration of the blood-brain barrier permeability. Hypobaria may contribute to AMS by causing blunting of ventilation, impaired lymphatic drainage from the lung and changes in autonomic functions. Current evidence does not support the role of generalised fluid retention, in the pathogenesis of AMS.

Clinical features

The predominant symptom of AMS is headache, which is generally frontal, throbbing, aggravated by exertion and more severe in the mornings. It is usually accompanied by insomnia, malaise, anorexia, nausea and vomiting. Symptoms typically start 4 to 6 hours after arrival at HA and usually subside within 72 hours with rest and no further gain in altitude.

Diagnosis

The Lake Louise Scoring System (LLSS) is commonly used to diagnose AMS. This consists of a self-reported questionnaire and physical examination (**Table 4**). A self-reported score greater than 4 or a total score greater than 5 suggests AMS.

Table 4: Lake Louise Scoring System for Diagnosis of AMS

Self-reported symptoms	
Headache

AMS diagnosed if self-reported score >4 or total score greater than 5

Treatment

The guidelines for management of AMS are shown in **Table 5**.

Table 5: Guidelines for Management of AMS

- Do not worsen the hypoxia
  - Avoid physical exertion
  - Prevent further gain in altitude
- Correct the hypoxia
  - Inhaled oxygen @ 2 to 4 L/min
- Treat symptoms
  - NSAIDs for headache
  - Anti-emetics for nausea/vomiting
  - Tablet Acetazolamide 250 mg, 8 to 12 hourly if symptoms severe
- If symptoms persist or worsen
  - Dexamethasone 4 mg 6 hourly, orally, IM or IV
  - Descend to lower altitude
    - Actual descent where possible
    - Simulated descent using recompression chambers

Complications

AMS may progress to HACE or HAPE, if not promptly managed or if the hypoxia is worsened due to physical exertion and/or a further gain in altitude.

Prognosis and prevention

AMS is usually a benign self-limiting condition if promptly recognised and treated. It can be prevented by slowing the rate of ascent to HA (**Table 6**) and by proper acclimatisation. Tablet acetazolamide (125 to 250 mg 12 hourly) started 24 hours prior to ascent to HA and continued for three days at HA is the drug of choice for prevention of AMS. Tablet dexamathasone (4 mg 6 hourly) can be considered in case of sulphonamide sensitivity but is not routinely recommended due to the potential complications of steroid therapy and interference with the normal acclimatisation process.

Table 6: Recommended Rates of Ascent at High Altitude

- Above 2,500 m to 3,000 m altitude:
  - Gain in sleeping altitude should not exceed 300 to 600 m per day
  - Allow one rest day for every 1,000 m gain in altitude
- Delay further ascent if symptomatic, wait till symptoms subside
- Descend to lower altitude if symptoms persist or deteriorate

High Altitude Cerebral Oedema (HACE)

Definition and epidemiology

HACE is a potentially fatal condition that can develop in an individual suffering from AMS or HAPE or can occur in isolation. It is defined as the onset of ataxia, altered consciousness or both in an individual who has AMS or HAPE. The incidence varies with altitude and ranges from 0.5% to 4%.

Aetiopathogenesis

The probable pathogenesis of HACE is as shown in (**Figure 1**).

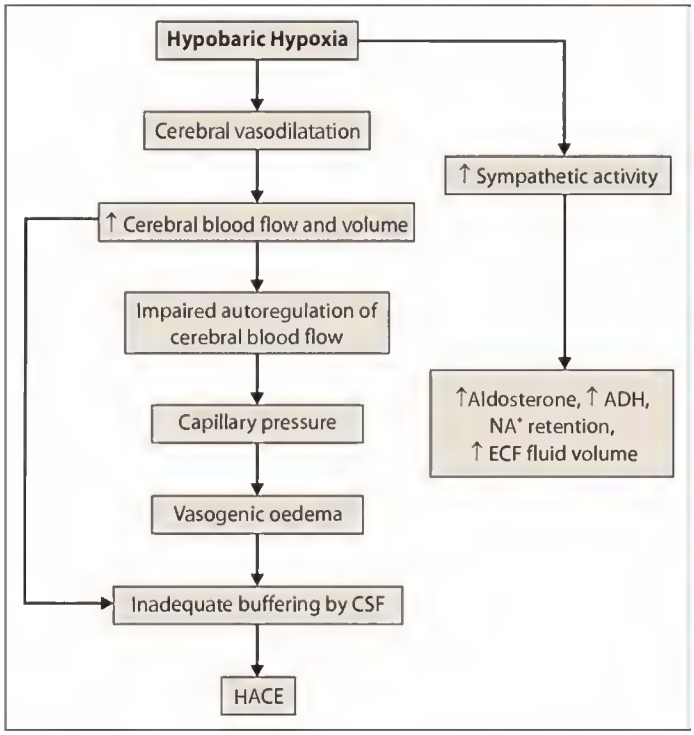

Figure 1: Aetiopathogenesis of high altitude cerebral oedema (HACE).
Source: Hackett PH, Roach RC. High altitude illness. N Engl J Med 2001; 345: 107-14.

Clinical features

A change in mental status and ataxia are the classical features of HACE. The former may range from lassitude, apathy and confusion to frank coma. Associated findings may include papilloedema, retinal haemorrhages and cranial nerve palsy.

Diagnosis

HACE is largely diagnosed clinically (**Figure 2**), since imaging facilities are rarely available at most HA locations. Where available, the magnetic resonance imaging (MRI) usually shows increased signal intensity in the region of the corpus callosum and splenium.

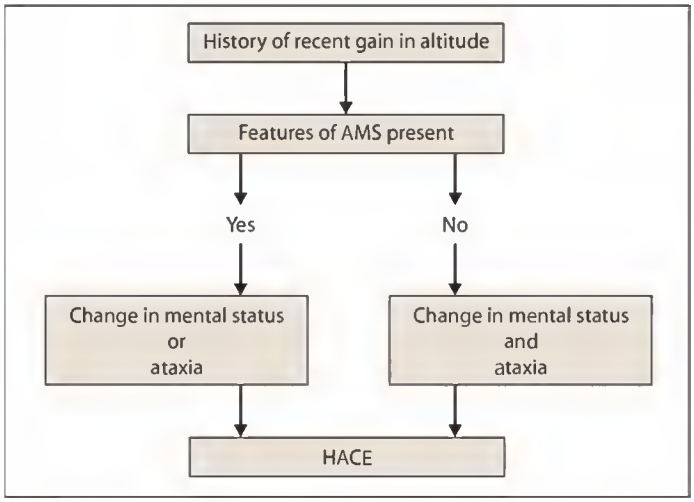

Figure 2: Algorithm for clinical diagnosis of high altitude cerebral oedema (HACE).
Source: Hackett PH, Roach RC. High altitude illness. N Engl J Med 2001; 345: 107-14.

Treatment

HACE is a medical emergency requiring immediate descent to lower altitude (**Table 7**). Simulated descent using recompression chambers can be life saving where actual descent is not possible. Portable recompression chambers, where available, can generate pressures up to 130 mm Hg and simulate a descent of about 6,000 ft (**Figure 3**).

Figure 3: An indigenously manufactured portable recompression chamber showing full pressurised state (130 mm Hg).

Table 7: Guidelines for Management of High Altitude Cerebral Oedema (HACE)

Do not worsen the hypoxia
- No physical exertion
- Prevent further gain in altitude

Correct the hypoxia
- Immediate descent to lower altitude
  - Actual descent where possible
  - Simulated descent using recompression chambers
- Supplemental oxygen via facemask at 2 to 4 L/min

Pharmacotherapy
- Dexamethasone 8 mg initially orally/IM/IV followed by 4 mg every 6 hours.
- Tablet acetazolamide 250 mg, 8 to 12 hourly if descent to lower altitude is delayed
- Injection mannitol to reduce intracranial pressure

Complications

HACE can be fatal if not managed as a medical emergency.

Prognosis and prevention

HACE is a life-threatening condition. The mortality may be as high as 25%, even with prompt institution of therapy. Prevention of HACE is by slowing the rate of ascent to HA (**Table 6**) and following a proper acclimatisation schedule.

High Altitude Pulmonary Oedema (HAPE)

Definition and epidemiology

HAPE is a non-cardiogenic pulmonary oedema characterised by pulmonary hypertension, leading to extravasation of fluid from the intravascular compartment in the lungs of healthy individuals with no underlying cardiac or pulmonary disease. HAPE usually occurs on the second or third day of arrival at HA. The reported incidence varies from 0.5% to 15%, depending on the rate of ascent and altitude reached.

Aetiopathogenesis

Elevated PAP due to hypoxic pulmonary vasoconstriction is central in the pathogenesis of HAPE (**Figure 4**). Exposure

of the basement membrane to the protein-rich oedema fluid results in secondary inflammation, activation of coagulation and generation of microthrombi in the lungs. Pre-existing inflammation may make the endothelium more prone to disruption. Vigorous physical exertion in unacclimatised individuals and exposure to low environmental temperatures may precipitate or aggravate HAPE by raising the PAP.

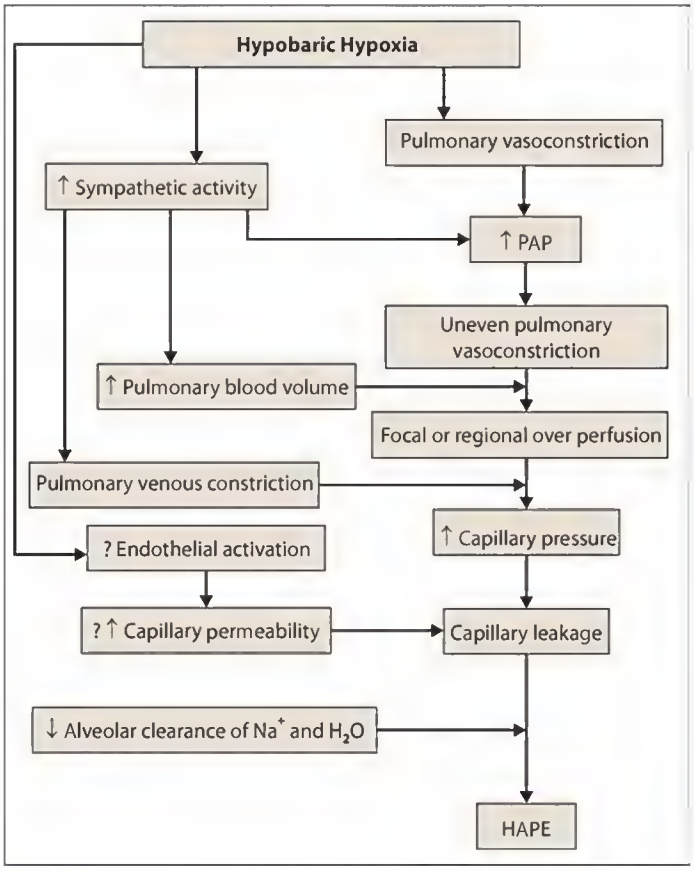

Figure 4: Aetiopathogenesis of high altitude pulmonary oedema (HAPE). *Source: Hackett PH, Roach RC. High altitude illness. N Engl J Med 2001; 345: 107-14.*

Clinical Features

Dry cough and reduced physical performance for the given altitude in an individual recently arrived at HA suggest HAPE. Dyspnoea and chest discomfort are common. Pink frothy sputum and respiratory distress occur later in the illness. Orthopnoea and haemoptysis are uncommon. Resting tachycardia and tachypnoea become pronounced as the illness progresses. Crackles and wheeze are usually present in more than one lung field.

Diagnosis

The clinical diagnostic criteria for HAPE are shown in **Table 8**. Investigations may reveal the following:

- ECG: Sinus tachycardia, right ventricular strain, right axis deviation, right bundle branch block (RBBB) and P wave abnormalities.
- Chest radiograph (**Figure 5**): Normal cardiac shadow, prominent pulmonary arteries and patchy infiltrates, generally confined to the right middle and lower lobes, may involve both lungs in severe cases.

Figure 5: Chest radiograph of a patient with high altitude pulmonary oedema showing non-homogenous opacities in the right middle and lower zones.

Table 8: Clinical Criteria for Diagnosing High Altitude Pulmonary Oedema (HAPE)

History of recent gain in altitude

WITH

Any two of the following symptoms:
- Cough
- Dyspnoea at rest
- Chest discomfort
- Weakness/fatigue

AND

Any two of the following signs:
- Crackles/wheeze in at least one lung field
- Central cyanosis
- Tachycardia
- Tachypnoea

Treatment

HAPE is managed as shown in **Table 9**. Elevated PAP usually reduces with correction of hypoxaemia. Drug therapy must be considered where administering oxygen and/or reduction of altitude is not possible. Nifedipine successfully lowers elevated PAP in most HAPE patients. Inhaled nitric oxide (NO) and phosphodiesterase inhibitors, such as sildenafil and tadalafil have shown promising results. Inhaled salmetrol has been reported useful in reducing PAP and improving oedema clearance.

Table 9: Guidelines for Management of High Altitude Pulmonary Oedema (HAPE)

Do not worsen the hypoxia
- No physical exertion
- Prevent further gain in altitude

Correct the hypoxia
- Descend to lower altitude
  - Actual descent where possible
  - Simulated descent using recompression chambers
- Supplemental oxygen via face mask @ 2 to 4 L/min

Pharmacotherapy to lower pulmonary artery pressure
- Nifedipine 10 mg orally followed by 30 mg sustained release 12 hourly

Complications

HAPE can be fatal if not recognised and treated promptly. Severe HAPE can worsen the hypoxaemia of HA and precipitate HACE.

Prognosis and prevention

HAPE can be managed with a mortality of less than 1% if recognised in time and promptly treated. Slowing the rate of ascent to HA and following a proper acclimatisation schedule can successfully prevent HAPE. Nifedipine (20 to 30 mg of extended release formulation 12 hourly) is advisable in susceptible individuals. Inhaled salmetrol has also been reported useful for prevention of HAPE.

Differential Diagnosis of Acute HA Illnesses

Many clinical conditions may mimic acute HA illnesses (**Table 10**). The diagnosis of AMS and HACE must be reconsidered if the onset of symptoms is after 3 days of arrival at HA, headache is absent, there is a rapid improvement of symptoms with fluid replacement or no improvement with oxygen therapy, acetazolamide, dexamethasone and descent to lower altitude.

Hyperventilation syndrome

SUBACUTE AND CHRONIC HIGH ALTITUDE ILLNESSES

Subacute Mountain Sickness (SMS)

Two distinct forms of SMS syndromes, which bear similarity with Brisket disease in cattle, have been described in humans.

Subacute Infantile Mountain Sickness (SIMS)

SIMS is reported predominantly in the Han Chinese living in Tibet. It occurs in infants born at lower altitudes and subsequently taken to HA. The prevalence increases with altitude and decreases with age. Symptoms start with poor feeding and lethargy, followed by dyspnoea, cough and signs of cardiac failure. SIMS is usually fatal. The pathophysiology involves muscularisation of pulmonary arterioles and medial hypertrophy of small pulmonary arteries, which is in contrast to concentric laminar intimal proliferation seen in primary pulmonary hypertension. The elevated PAP results in right ventricular hypertrophy and cardiac failure. Prompt reduction of altitude can lead to complete resolution of the condition.

Subacute Adult Mountain Sickness (SAMS)

SAMS was first described in 1990 in Indian soldiers stationed at extreme altitude for 3 to 6 months. Symptoms begin with shortness of breath and edema and progress to gross anasarca. Patients show features of severe congestive cardiac failure with right ventricular hypertrophy, right axis deviation and T wave inversion in leads V_1 to V_6. The pathophysiology includes severe pulmonary arterial hypertension coupled with polycythaemia, possible myocardial dysfunction and alteration in body fluid homeostasis. Abnormalities return to normal within 12 to 16 weeks of descent to lower altitude.

Chronic Mountain Sickness (CMS) or Monge's Disease

Definition and epidemiology

First described by Carlos Monge in 1925, the consensus statement of the VI World Congress on Mountain Medicine 2004 defines CMS as a clinical syndrome that occurs in HA natives or long term residents at altitudes above 2,500 m, characterised by excessive erythrocytosis, severe hypoxemia and in some cases moderate/severe pulmonary arterial hypertension, which may result in *cor pulmonale*, leading to congestive cardiac failure. The reported incidence of CMS in Tibetans is 0.91%.

Aetiopathogenesis

CMS was attributed to a loss of acclimatisation in already acclimatised individuals; however, a low hypoxic ventilatory response is no longer considered an important aetiological factor. A likely possibility is markedly raised erythropoietin (EPO) levels. The raised haematocrit due to elevated EPO raises blood viscosity, worsens tissue hypoxia, and results in further elevation of EPO levels and genesis of a vicious cycle. Patients of CMS also have increased PAP, possibly due to elevated blood viscosity.

Clinical features

The clinical features of CMS are shown in **Table 11**.

Table 11: Clinical Signs and Symptoms of Chronic Mountain Sickness (CMS)

Symptoms
Headache
Breathlessness
Dizziness
Palpitations
Sleep disturbance
Fatigue
Localised cyanosis
Burning of palms and soles of feet
Dilatation of veins
Muscle and joint pains
Anorexia
Lack of mental concentration
Alterations in memory
Clinical/Investigative findings
Excessive erythrocytosis
Haemoglobin ≥19 g/dL in females and ≥21 g/dL in males
Raised pulmonary arterial pressure (not mandatory)
Features of heart failure (not mandatory)
Chest radiograph
Prominent pulmonary arteries
ECG
Right ventricular hypertrophy
Right atrial enlargement
Proteinuria

Diagnosis

CMS is diagnosed clinically (**Table 11**) in patients living at altitudes greater than 2,500 m, with normal lung function and without chronic pulmonary or other medical conditions that worsen the hypoxaemia.

Treatment

Descent to lower altitudes is the treatment of choice. Other modalities of treatment have variable results (**Table 12**).

Table 12: Guidelines for Management of Chronic Mountain Sickness (CMS)

Migration to lower altitudes is the treatment of choice
Other modalities of treatment with variable results
Phlebotomy to reduce haematocrit
Oxygen supplementation and respiratory training
Calcium channel blockers to reduce pulmonary artery pressure
Inhaled nitric oxide 40 ppm or nitric oxide 15 ppm with 50% oxygen to lower pulmonary artery pressure
Medroxyprogesterone 20 to 60 mg/day for 10 weeks to stimulate ventilation
Tablet acetazolamide 250 mg/day for 3 weeks

Complications and prognosis

CMS may result in cor pulmonale and congestive cardiac failure. Migration to lower altitude corrects the hypoxaemia and haematocrit returns to normal in 2 to 3 weeks. Right ventricular hypertrophy and elevated PAP normalise in about two years.

High Altitude Pulmonary Hypertension (HAPH)

Definition

HAPH is a clinical syndrome characterised by raised mean or systolic PAP, right ventricular hypertrophy, cardiac failure, moderate hypoxaemia and absence of excessive erythrocytosis. It occurs in HA residents with no underlying cardio-pulmonary disease.

Aetiopathogenesis

Remodelling of the pulmonary vasculature with muscularisation of pulmonary arterioles is the likely cause of the raised PAP. The elevated blood viscosity due to erythrocytosis is probably a contributory factor.

Clinical features

HAPH presents with dyspnoea, cough, cyanosis, sleep disturbance, irritability and features of right heart failure.

Diagnosis

HAPH is diagnosed as shown in **Table 13**, after ruling out other cardio-pulmonary causes of pulmonary hypertension.

Treatment

Descent to lower altitude is desirable. The raised PAP can be reduced using calcium channel blockers (Nifedipine 20 to 30 mg 12 hourly), inhaled NO (15 ppm with 50% O_2 or 40 ppm for 15 min), phosphodiesterase inhibitors and prostaglandins.

Complications and prognosis

Prompt descent to lower altitudes improves symptoms and the PAP returns to normal in 2 to 6 months. Untreated, the condition results in right heart failure.

Table 13: Diagnostic Criteria and Investigation Findings in High Altitude Pulmonary Hypertension (HAPH)

Raised pulmonary artery pressure
Mean pulmonary artery pressure >30 mm Hg
Systolic pulmonary artery pressure >50 mm Hg
Haemoglobin
Males <21 g/dL
Females <19 g/dL
Chest radiograph
Cardiomegaly—enlargement of right atrium and right ventricle
Prominent central and peripheral pulmonary arteries
ECG
Right axis deviation
Right ventricular hypertrophy
Echocardiography
Signs of right ventricular hypertrophy/failure

MISCELLANEOUS ILLNESSES AT HIGH ALTITUDE

High Altitude Retinal Haemorrhages (HARH)/Altitude Retinopathy

Definition and epidemiology

HARH are haemorrhages of the inner and middle layer of the retina seen in lowlanders on ascent to altitudes beyond 5,000 m. HARH is rare below 3,000 m and does not occur in HA natives. When accompanied by vascular dilatation, tortuosity and optic disc hyperaemia, it is referred to as 'altitude retinopathy'. HARH may occur in association with other acute HA illness. The average incidence at altitudes beyond 5,300 m is 34%.

Aetiopathogenesis

Increased retinal blood flow and increased vascular endothelial permeability are the most likely aetiological factors. Exercise in hypoxia may aggravate the increased retinal vascular permeability.

Clinical features

Most HARH are asymptomatic. Those occurring near the fovea may produce positive scotomas.

Diagnosis

HARH usually spare the macula and occur near the superior and inferior temporal arcades. They may range from 'red flame shaped' lesions to 'dot and blot' haemorrhages. 'Cotton wool spots' have also been reported as isolated findings or associated with overlying retinal haemorrhages, especially at altitudes greater than 7,000 m. Associated findings may include dilated retinal vessels and optic disk hyperaemia.

Treatment

Spontaneous resolution within days to weeks is the rule and no active treatment is required. Descent to lower altitude is advisable if the haemorrhage appears to be enlarging on daily examination.

Thrombotic Episodes at High Altitude

Thrombotic episodes generally occur at EA and usually present as deep vein thrombosis, portal vein thrombosis, pulmonary thrombo-embolism, and stroke. Limited studies investigating haemostasis at HA have largely been inconclusive. Hypoxia *per se* does not present a special risk for thrombosis. Other factors that might possibly contribute to thrombotic episodes include

dehydration, polycythaemia, immobility due to poor weather conditions and constrictive clothing. Individuals with deficiency of coagulation inhibitors, such as protein C, may be at an increased risk. The role of elevated homocysteine levels in the pathogenesis of this condition at HA is under investigation. Thrombotic episodes are managed as per conventional guidelines and prevented by addressing the known risk factors mentioned above.

Gastrointestinal (GI) Problems at High Altitude

Apart from the nausea and vomiting of AMS and diarrhoea related to poor hygiene and sanitation, flatulence, dyspepsia and anorexia are common at HA. The aetiology is multifactorial including the role of hormones like leptin and cholecystokinin and the effect of hypoxia on GI motility. Malabsorption of fats occurs at altitudes beyond 5,000 m. Upper GI bleeds are common at HA due to increased capillary friability. The indiscriminate intake of nonsteroidal anti-inflammatory drugs (NSAIDs) for treatment of AMS may precipitate the condition. A carbohydrate rich diet is recommended at HA, being the preferred metabolic substrate. An increase in the daily caloric intake of 400 to 500 kcal is necessary to maintain sea level body weight in lowlanders at HA.

Effect of Solar/Ultraviolet (UV) Radiation

Acute exposure to increased levels of solar and UV radiations at HA primarily affects the eyes and skin, resulting in snow blindness and sun burns.

Snow blindness occurs due to exposure of the corneal epithelium to UV rays resulting in solar keratitis and blistering of the corneal epithelium in severe cases. It is characterised by photophobia, blepharospasm and intense conjunctival congestion. Anaesthetic eye drops and analgesics for reducing the pain and application of an eye ointment and patch for 24 hours are the principal modalities of treatment. Prognosis is generally very good. Snow blindness can be prevented by using UV protective eyewear with side protectors. Sunburns can be prevented by reducing the time and amount of skin exposed to direct sunlight and by using sun screen lotions.

27.9 Aviation Medicine

JS Kulkarni

INTRODUCTION

Aerospace medicine is a multifaceted speciality, which not only deals with basic subjects like physiology and biochemistry but also deals in ophthalmology, otorhinolaryngology, aviation neuropsychiatry and pathology. Human engineering, ergonomics, biomedical, bioelectronics and aeronautics being other facets of this specialty. Unlike other streams of medicine where a doctor deals with unhealthy individuals in a healthy environment, the subject of aviation medicine deals with healthy subjects in most hostile environment, i.e. high altitude and space. Aviation stressors adversely affect the aircrew, the passengers and invalids alike. Therefore, augmenting the physiological reserves and meticulous preparation before travel are the only antidotes to the destabilising environment. The physiological consequences of rapid ascent to high altitude form the core issue in aerospace medicine.

The pressure exerted by the atmosphere (barometric pressure) falls exponentially with altitude producing a proportional decrease in the partial pressure of oxygen and other constituent gases. The pressure falls to half (387 mm Hg) of its value at an altitude of 5.48 km (18,000 ft); becomes one quarter (190 mm Hg) at 10.27 km (33,700 ft) (**Figure 1**). By about 30.48 km (100,000 ft), it becomes one-hundredth of that at sea level. The temperature in the atmosphere falls at a steady rate of about 2°C per 0.3048 km (1,000 ft); in the troposphere. This is known as the lapse rate. Thus, from an average 15°C at surface of earth it becomes –56.5°C at 12.19 km (40,000 ft); after which it becomes steady in the ozone layer.

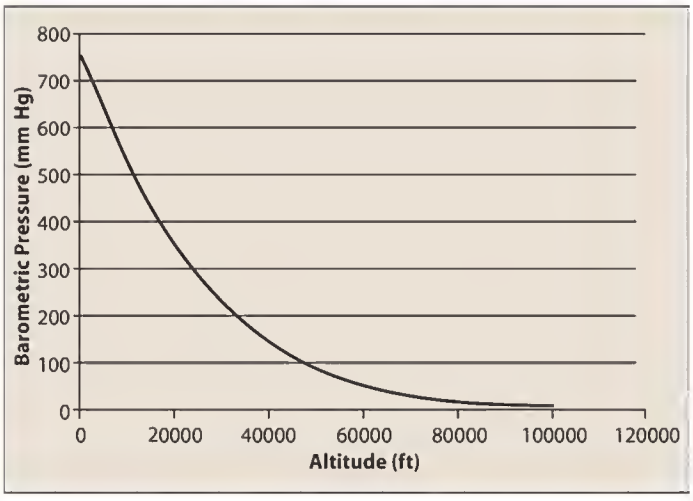

Figure 1: Barometric pressure change at rising altitude.

STRESSORS IN AVIATION ENVIRONMENT

The various stressors adversely affecting the aircrew and passengers are enumerated in **Table 1**.

Table 1: Stressors in Aviation Environment

Physical stressors	Heat, cold, humidity, noise, vibration, radiation
Physiological stressors	Hypoxia, decompression sickness, hypobaria, acceleration, motion sickness, disorientation and barotraumas
Psychological stressors	Mental workload, task saturation, poor communication and circadian disturbances
Personal stressors	Drugs, alcohol, smoking, disease, anxiety

HYPOXIA

Hypoxia is acknowledged as the single most serious physiological hazard encountered in flight at altitude. Aviation-induced hypoxia is largely hypobaric hypoxia. Hypoxia affects all systems but the main effects are on the respiratory, cardiovascular and neurological systems. These effects are much less if the human body follows the acclimatisation/adaptation process. It stimulates respiration and induces hyperventilation. Hypoxia causes an increase in heart rate with increase in cardiac output; vasodilatation in vascular beds increases the blood flow to the heart and brain while less vital parts are deprived. Cerebral circulation is sensitive to PaO_2 and $PaCO_2$. There is vasoconstriction of pulmonary vascular bed, which results in a raised pulmonary artery pressure in the presence of increased cardiac output. Gross reduction in fall of PaO_2 results in unconsciousness. Reduction of psychomotor function evidenced by diminished eye-hand coordination, reduced choice reaction time, increase in muscular in-coordination and increase in simple reaction time occurs with increasing altitudes in the said order. Cognitive function impairment seen as impairment of performance of novel tasks and memory impairment occurs between 2.44 and 3.048 km (8,000 and 10,000 ft). Visual function deterioration seen as reduction in perceived light intensity, diminished visual acuity, raised light perception threshold and tunnelling of vision starts at altitudes of 1.52 km (5,000 ft) and increases progressively. The effects of hypoxia depend primarily on the rate of ascent, duration of the stress and are also affected by physical activity (exercise exacerbates), ambient temperature (cold reduces tolerance), intercurrent illness, smoking and drugs. Hypoxia can be prevented by single or a combination of following; flying in physiological region, i.e. up to 2.44 km (8,000 ft), i.e. helicopters, gliders and microlites, pressurising the cabin to physiological levels (as seen in commercial airlines) and oxygen supplementation by way of oxygen mask, beginning at 3.048 km (10,000 ft) and given exponential increase of oxygen-enriched air till at an altitude of 10.27 km (33,700 ft) when 100% oxygen will be required. Beyond 12.19 km (40,000 ft),

oxygen is required to be administered under pressure and beyond 13.72 km (45,000 ft) aircrew need to do supportive pressure clothing as worn by astronauts.

DECOMPRESSION SICKNESS

Decompression sickness is a syndrome produced due to supersaturation of body tissues with nitrogen due to falling partial pressure of alveolar nitrogen. This leads to formation of nuclei, which expand into bubbles that give rise to the clinical picture, which may include aviators bends (joint and limb pains), chokes (respiratory disturbances), creeps (itchy, blotchy rash, formication), visual disturbances like blurring of vision, scotomas and fortification spectra, staggers (neurological disturbances). Lastly, cardiovascular or neurocirculatory collapse can occur which is an emergency condition and the recovery is accompanied with vomiting and frontal headache. The severity of symptoms depends on the altitude at which the decompression occurs, duration of exposure, the rate of ascent to altitude, hypoxia and personal variables like age, body build, obesity, physical activity and previous injury.

BAROTRAUMA

In accordance with Boyle's law, any gas in a closed/semi-closed cavity would expand when ambient pressure reduces and *vice versa*. Expanded gases in closed cavities cause severe discomfort. This pressure-induced trauma is termed as barotrauma. Generally, lungs are not affected as the expanded gases vent out through the trachea and oropharynx to the atmosphere. Expansion of gases in small intestine may cause pain and discomfort but in the large intestine they get expelled as flatus. Avoiding gas-forming foods like beans, cauliflower, carbonated beverage and alcohol help preventing this disability. Otitic barotrauma is the most common form of barotrauma. On ascent, the expanded air in the middle ear cavity escapes through the Eustachian tube into the pharynx; however, during descent it is difficult to equalise the pressure between the middle ear and the pharynx, more so in presence of upper respiratory infection. Discomfort progresses to acute severe pain and may finally end in a retracted/ruptured tympanic membrane. Eustachian tube can be forced open by simple methods like swallowing, sucking on a candy, yawning, moving the jaw from side to side or Valsalva manoeuvre (forced expiration against a closed glottis, while mouth is closed and nose pinched). Otitic barotrauma is treated with analgesics, nasal decongestants and broad-spectrum antibiotics. Similarly, sinus barotrauma is the trauma of the paranasal sinuses. During ascent, air vents easily through ostia of paranasal sinuses but during descent the ostia are readily occluded if individual is suffering from upper respiratory catarrh. The symptoms are a sudden severe pain in affected sinuses, which continues if the descent is not halted and may lead to epistaxis. The management is similar to otitic barotrauma.

ACCELERATION STRESS

Fast moving aircraft impose accelerative stress (1G = 978 cm^{-2}, i.e. acceleration due to earth) and reactive inertial stress on the body. Depending on the direction these forces act, they are classified into + G and – G in the x axis (front-back), y axis (left-right) and z axis (head-foot). Accelerative stress are within the tolerance level of the human body and do not pose a problem except to a small group of military fighter aircrew who while performing aerial manoeuvres far exceed the human tolerance to G forces like in executing sharp turns or performing loops/sharp dives. The first effect of +Gz acceleration is increase in body weight; although muscle power remains same the movements become increasingly difficult. At around +3 to +4 Gz head stoops down and upward movement of hands becomes difficult. The second effect is increase in hydrostatic pressure which forces blood into the abdomen and lower limbs and lasts as long as acceleration operates. Thus, circulating blood becomes less and there is fall of blood pressure above the level of heart. Eyes and brain suffer most. Between +3 and +4 Gz one suffers from a condition called 'gray out' if continued after 10 seconds, this causes the vision to become hazy and constricted as if looking through a foggy tunnel. The vision completely fails between +4 and +5 Gz producing 'blackout'. The blood pressure at eye level is not enough to overcome pressure inside the eyeball causing temporary blindness. Beyond +5 or +6 Gz unconsciousness occurs due to temporary stoppage of blood supply to brain. This phenomenon is also described as G induced loss of consciousness. The effects of 'blackout' disappear almost as soon as the G level is reduced, although the individual may be confused for a few seconds. Protection against this can be achieved by a combination of the following methods; a posture where the distance from the heart to the brain is reduced, viz. use of tilt back seats, voluntary manoeuvres like anti-G straining manoeuvre which raises the intra-abdominal pressure thereby maintaining the level of the diaphragm and helping in venous return to the heart and lastly the use of anti G-suits where a number of inter-connecting bladders located over the abdomen, thighs and calves expand and compress the major vascular bed below the heart-level and help maintain the level of the diaphragm and prevent extravascular loss of fluids. All these methods act synergistically and help the aircrew in overcoming the stress of accelerative forces.

NOISE AND VIBRATION

Noise and vibration are inbuilt side effects of flying. Both produce physical, physiological and psychological stress which is not of consequence individually, but may add to the overall stress of flying. Outside an aircraft the noise levels may be as high as 110 decibels. Military aircrew protect themselves from noise by helmet-headset, ground crew by ear-defenders/earmuffs and passengers by the cabin conditioning and noise abatement technologies. Vibration is more so a problem in helicopters but mild vibratory stress may however be present due to buffeting in air pockets, poor maintenance and inbuilt defects in civil airliners as well. Low backache and fatigue are the two main problems encountered due to vibration.

MOTION SICKNESS

Motion sickness occurs on exposure to real or apparent, unfamiliar motion to which the individual is not adapted. The common symptoms of air sickness are stomach awareness or discomfort in abdomen, cold sweats on forehead, neck, armpits and palms, hyperventilation, salivation, warm sensations in some parts of the body, giddiness or dizziness, apathy and lack of desire to continue activity, nausea and vomiting. In mild cases there may be only nausea and no vomiting. The eyes, vestibular and proprioceptive senses are the main inputs to the brain to assess motion and in a flying environment unresolved, strong

motion cues mediate motion sickness. Although drugs like scopolamine, promethazine, dimenhydrinate, cinnarizine have been tried with success in the prevention and management of motion sickness but may not be suitable for aircrew due to their side effects. Generally desensitisation programmes in which the individual is gradually exposed to conflicting motion inputs, which desensitise the vestibular system and adjuvant psychotherapy and relaxation techniques further help the process treat motion sickness.

SPATIAL DISORIENTATION

Spatial disorientation (SD) refers to an individual's inability to appreciate his true position in relation to the surface of the earth. Thus, a disorientated pilot is uncertain or unaware of his position or the attitude of his aircraft. The triad of orientation, i.e. eyes, vestibular system (otoliths and semi-circular canals) and proprioception are adversely affected in the flying environment and give rise to false sensations and disorientation. SD can often lead to disastrous errors and accidents. Factors like fatigue, inexperience, hypoxia, alcohol, drugs, emotional stress, lack of visual cues (cloud flying, night flying, etc.) and changeover from visual to instrumental flying and *vice versa* aggravate disorientation. Proper selection of candidates, suitable indoctrination and training and instrument flying practice help in prevention of SD. It is pertinent to remember that no one is immune to SD.

CIRCADIAN DESYNCHRONISATION

Circadian or biological rhythms have an inherent rhythmicity of 24 hours using signals of light and darkness, noise etc. Circadian desynchronisation is the failure of the human body to adjust its own routine to a clock that may bring darkness up to 10 hours earlier or later than usual. Eating, sleeping, excretion may be adversely affected and mental reactions may be slowed down considerably. These changes are more pronounced in eastbound flights. Generally a day of recovery is required for every 5-hour time change. Thus, one should attempt to sleep as close to the usual bedtime as possible. For both civil and military aircrew, the problem is more since they need to fly the aircraft as well. Preventive measures include appropriate scheduling of the work and rest periods and resynchronisation using timed exposure to artificial bright light.

ANTHROPOMETRY IN AVIATION

Anthropometry is the science of human measurements, which includes measurement of the body dimensions and other physical characteristics of the body like volumes, centre of gravity and mass of body segments. In static (anatomical) anthropometry fixed structural dimensions of the body between two specific anatomical landmarks are measured like height, arm length and contour dimension like biceps girth. In dynamic (functional) anthropometry dimensions are taken when the body is engaged in some activity, e.g. clearance, reach, range of movements of joints and strength of various actions. Anthropometry has significant application in aviation; selection of right candidate for pilot training, designing of cockpit work place, designing of ejection systems and instrument panels, improve pilot comfort and convenience and identification of bodies in aircraft accidents, fitment of flying clothing and evaluation of orthopaedic disabilities.

SPACE MEDICINE

In space, apart from hypobaria, hypoxia and acceleration the most important issue is of weightlessness. Microgravity challenges the cardiorespiratory, haematological, musculo-skeletal and immune system. Motion sickness, radiation effects, psychological and interpersonal factors (depression, anxiety and crew tensions), nutrition, personal hygiene and waste management are a multitude of other factors, which need considerable attention. 'Weightlessness' is nearly impossible to recreate on earth but certain aspects can be simulated like fluid shifts seen in space, cardiovascular changes, musculoskeletal changes, etc. The techniques employed in our country for studying few of the aspects of weightlessness are dry immersion, head-down tilt, lower body negative pressure (LBNP), head-up tilt and stabilo-platform.

CASUALTY EVACUATION

Transportation of critically ill and injured is an important health care adjunct. Foremost it is important to ascertain that air evacuation outweighs the risk of not being moved. Stabilisation of vital parameters and financial constraints are other issues that govern the decision of air evacuation. Priority one patients are those whose airlift is necessary to save life or limb, priority two are patients whose condition will be adversely affected if not evacuated or those needing specialised treatment, priority three are patients whose prognosis would benefit if transported by air and priority four are those for whom movement by air is a matter of convenience. Some medical conditions need special assessment prior to evacuation by air; acute myocardial infarction should ideally not be evacuated by air for at least 6 weeks. In a fully compensated cardiovascular condition, a cabin altitude of 3.048 km (10,000 ft) is well tolerated, but in borderline cases, supplemental oxygen will be required whenever cabin altitude rises above 1.37 km (4,500 ft). Untreated pneumo-thorax is absolute contraindication. In pneumonia, gaseous exchange in alveoli is disturbed, therefore, supplemental oxygen will be required from ground level itself. Patients with increased intracranial pressure need supplemental oxygen to eliminate the risk of minimal hypoxia. Pulmonary burns need to be excluded in all cases of burns. In-patients, who have undergone abdominal surgery recently, gases may remain trapped in the abdominal cavity and create problem. Also, trapped gas in a hernia or volvulus can expand in-flight causing pain, and in some cases compromise the circulation of the bowel. Notwithstanding all these limitations the specific advantages of air evacuation are far more significant; morale boosting, saving of time, early institution of specific and definitive treatment, reduced incidence of infection, overcoming adverse terrain and centralisation of trained medical expertise being few of them.

REGULATIONS RELATED TO AVIATION MEDICINE

The responsibility of assessing the medical fitness and laying down medical standards for the military aircrew of India rests on the Director General of Medical Services (DGMS) of the Indian Air Force. Medical fitness of all civil flight crew is not just a requirement of the International Civil Aviation Organisation (ICAO) agreement to which India is a signatory but is controlled

by the Director General Civil Aviation (DGCA), which is of considerable public interest and importance as well. In India, medical examinations for all commercial flight crew are conducted at designated Indian Air Force medical centres, whereas for private license holders medical examinations can be conducted by DGCA approved class II aviation medical examiners. All medical examinations are conducted in accordance with ICAO standards and recommended practices (Annex 1). ICAO, a specialised agency of the United Nations set up to promote safe and orderly development of civil aviation in the world, sets international standards and regulations necessary for safety, security, efficiency and regularity of air transport and serves as the medium for cooperation in all fields of civil aviation among its 185 contracting nations. India is a signatory to the ICAO convention and, hence, is committed to adopt at the minimum the ICAO standards and recommended practices.

AEROMEDICAL RESEARCH

Research in the field of aerospace medicine has been going on since last five decades or so. In the initial years, the research was oriented towards thermal stress, physiological limits of human tolerance and acceleration physiology. With advancing technology the newer problems related to human engineering, disorientation, flying clothing and psychological aspects of flying came under the ambit of research. Currently, the research is more of an applied nature, oriented towards operational efficiency and flight safety. The Armed Forces Medical Research Committee, and the Human Engineering Panel of Aeronautical Research and Development Board and Indian Council of Medical Research support research in aviation medicine. Long duration flying and disorientation desensitisation are the newer fields of research. The aviation medicine specialists also render Human Engineering Consultancy related to aircraft design and promotion of flight safety through aircraft accident investigations for military and civil aircraft.

27.10 Radiation Hazards

AM Samuel

An understanding of the biological effects of nuclear and X-ray radiation is important for evaluating their potential uses and dangers. This is pertinent in the present scenario of technology advances wherein X-rays in the form of computed tomography (CT), positron-emission tomography (PET)-CT and radioisotopes are being used extensively in diagnosis and therapy and also due to recent incidence of Fukushima nuclear disaster in Japan.

Certain radiations are more damaging than others. Alpha radiation is the most damaging to human tissues because its particles are strongly ionising. Neutrons are also damaging to cells, because they interact very easily with body tissue which contains a lot of water. These are a highly penetrating form of radiation. Beta and gamma radiation are the least damaging forms of nuclear radiation but these are able to penetrate deeper into the body than alpha radiation. Gamma radiation and X-rays pass through the body easily.

This chapter will not cover hazards due to ultraviolet, infrared and microwave radiations but relate to ionising radiations only.

BACKGROUND RADIATION

It is important to know that one is constantly being exposed to a variety of natural and man-made background radiations. There is exposure of gamma rays from space and from the earth as cosmic radiation which is equal to 1 mSv per year on earth and 27 mSv per year in space. Cosmogenic radionucleides (C14, Be7 and He3) account for 0.28 mSv per year and natural exposures accounts for 0.1 mSv per year. Radioactive potassium 40 atoms are naturally present in the body and undergo several thousand nuclear disintegrations every second. This accounts for 0.26 mSv per year. Medical exposures account for 20%, and natural background exposures for 80% of average exposures to world populations.

IONISING RADIATION

A wide variety of ionising radiations can interact with biological systems, but there are only 5 types of radiation of importance and these are gamma, neutron, beta, alpha and X-rays.

Gamma Radiation

Gamma radiation which emanates from the nucleus of an atom is highly energetic, penetrating so that a significant part will pass through the human body without interaction. This energy deposition may occur anywhere along a given photon's path. Because of its penetrating ability, the effects of gamma irradiation can be independent of the location of the source, (i.e. internal or external to the body).

Gamma rays are commonly used for diagnostic and therapeutic purposes.

Neutron Radiation

Since neutrons are uncharged particles and can react only with the nuclei of target atoms, the probability of interaction of neutrons in the energy range is roughly comparable to that of low-energy gamma photons. The energy deposition will not be uniform.

Its present clinical application is in neutron beam therapy for the treatment of some forms of cancer.

Beta Radiation

High speed electrons in the form of beta radiation lose most of their energy after penetrating only a few millimeters of tissue. If the beta emitting material is on the surface of the skin, the resulting beta irradiation causes damage to the basal stratum of the skin. Damaged cells may be of greater significance to the total organism than killed cells, particularly if they go on to become malignant or otherwise malfunction. Killed cells are replaced quickly in most tissues with any degree of reserve capacity and do not cause significant overall clinical effects unless the cells involved are highly critical or the fraction of cells killed in a given organ is large. Beta rays are used in radioisotope therapies.

Alpha Radiation

The energy of these relatively heavy, positively charged particles is fully absorbed within the first 20 micrometers of an exposed tissue mass. Because of this, alpha radiation is not an external hazard. If alpha emitting material is internally deposited, all the radiation energy will be absorbed in a very small volume of tissue immediately surrounding each particle. These rays are highly effective in targeted radioisotope therapies.

There is now a significant progress in the development of radioisotope therapies which are internally administered and are effectively targeted to the cancerous tissues. In such situations, beta and alpha rays which can deposit their energy in a small volume of tissue will be useful and can reduce radiation exposure to the normal surrounding tissues.

X-rays

X-rays, which origin is from the electron shells of the nucleus of an atom, are a type of penetrating radiation that, depending on the dose, can reduce cell division, damage genetic material, and harm unborn children. X-rays are extensively used for diagnostic purposes.

INTERACTION OF IONISING RADIATION WITH MATTER OR TISSUES

When radiation interacts with target atoms, energy is deposited, resulting in ionisation or electron excitation. This ionisation or excitation must involve certain critical molecules or structures in a cell. It has been theorised that this localisation of absorbed energy in critical molecules could be either a direct or an indirect action.

However, the most reasonable hypothesis is that in an indirect reaction, water, both intra-cellular and extra-cellular, is the

primary site of radiation energy deposition and that the energy deposited in the water would be transferred to and affect sensitive molecules indirectly. This is done through the production of a variety of *free radicals,* such as superoxides, oxygen, hydrogen and hydrogen peroxide radicals which are highly reactive and which damage chemical bonds in molecules. Direct action is at the level of the chromosomes of the cell nucleus.

Units of Exposure and Dose

The need to quantify radiation damage became increasingly evident, despite obvious difficulties in doing so. The first two units introduced dealt with radiation in the air, and as it is absorbed in living tissue. The two corresponding quantities are called 'exposure' and 'absorbed dose'.

The unit of radiation 'exposure', adopted by the International Congress on Radiology in 1931, was the Roentgen. *A roentgen* is a quantity of X-rays or gamma-rays which will cause a precisely defined degree of ionisation in 1 kg of dry air.

The roentgen unit does not apply to any particulate radiation (such as, alpha, beta, neutron or high-speed ions), nor does it involve biological tissues. To rectify these shortcomings, the concept of *'absorbed dose'* was introduced. The unit of absorbed dose is called *a Rad* (an acronym for radiation absorbed dose).

One rad is that quantity of ionising radiation of any type that will deposit 100 ergs of energy in each gram of absorbing tissue.

The *relation between 'exposure' and 'absorbed dose'* depends on the tissue involved. The rad has now been replaced by the *Gray (Gy)* which equals to 100 rads.

Relative biological effectiveness (RBE)

Equal doses of ionising radiation are not always equally effective in causing biological damage. Such observations have led to the concept of RBE. In any given situation, when two different doses of ionising radiation produce the same measurable biological result (e.g. number of mutations, reduction in lymphocytes, incidence of cancer, degree of mental retardation, percentage of animals killed promptly) is the RBE of radiation.

Linear energy transfer (LET)

One important consideration affecting RBE is the 'quality' of the ionising radiation being used: In general, a given dose of alpha or neutron radiation is much more effective in causing biological damage than an equal dose of beta, gamma or X-ray radiation. This difference in effectiveness is related to a physical quantity called LET noted as high and low LET radiations.

Units of dose equivalence: the quality factor (Q)

In an attempt to account for such differences in biological effectiveness, a new unit of 'dose equivalence' was introduced, *called a Rem (an acronym for 'Roentgen Equivalent Man').* This unit is intended to indicate, however roughly, the relative degree of biological damage caused by a particular exposure to ionising radiation. The rem is now superceded by the *Sievert (Sv); 1 Sv = 100 rem.*

What is an effective dose of radiation?

Finally, the biological effect of radiation depends on the type of tissue being irradiated.

When radioactive materials are incorporated into the body by inhalation, ingestion, and absorption through the skin and retained, significant radiation injury can be sustained by specific tissues in which the materials are concentrated or in some instances by the whole body. The primary factors which determine the type and degree of injury are the types and amounts of the isotopes deposited and the nature and energies of the radiation emitted.

In the context of a growing use of radio-isotopes for diagnosis and therapy, one needs to understand the kinetics of the administered radio-isotope which is generally tagged to compounds for specific purposes.

A radioactive material internally administered must be eliminated from the body to remove its hazards. This can be achieved by the following procedures:

- Include renal excretion for most soluble materials;
- Elimination in the faeces for materials which are retained in the gut or which can be secreted in the bile;
- Exhalation for volatile materials and gases.

The rate at which a material is eliminated is usually expressed as *'the biological half-life'*. This is the time it takes for one-half of a given amount of material to be excreted or eliminated. The biological half-life may be variable. *'Effective half-life will be a function of their physical and biological half-lives considered together'.*

In the event of excess radio-isotopes either due to mis-administration or accidents, methods for detoxification are needed.

Chelating agents, e.g. calcium or zinc diethylenetriamine pentaacetic acid (DTPA), if administered soon after the exposure, are effective in enhancing the elimination of certain radio-isotopes not fixed in tissues. Potassium iodide or iodate if given prior to or soon after an intake of radio-iodine, will reduce the uptake of radio-iodine by the thyroid gland. Similarly, orally administered Prussian Blue will reduce the absorption of cesium from the gut and alginate will reduce strontium absorption.

CELLULAR EFFECTS OF RADIATION

Mechanisms of Damage

Injury to living tissue results from the transfer of energy to atoms and molecules in the cellular structure. Ionising radiation causes atoms and molecules to become ionised or excited. These excitations and ionisations can:

- Produce free radicals.
- Break chemical bonds.
- Produce new chemical bonds and cross-linkage between macromolecules.
- Damage molecules that regulate vital cell processes (e.g. deoxyribonucleic acid (DNA), ribonucleic acid (RNA), proteins).
- The cell can repair certain levels of cell damage. At low doses, such as that received everyday from background radiation, cellular damage is repaired rapidly.
- At higher levels, cell death results. At extremely high doses, cells cannot be replaced quickly enough and tissues fail to function.

Tissue Sensitivity

An important factor which is an individual response of a cell to radiation induced changes at the cell level is the parameter called tissue sensitivity. Hence, all individuals will not react identically to the same dose of radiation. Some individuals will be more sensitive to radiation than others. Hence, this aspect needs to be understood especially when therapy with radiation is considered.

The probable reason is a balance between damage to tissue and the capability for tissue repair. Some individuals will have a better ability for repair than others and the final outcome would be reflection of this balance in an individual.

Radiation sensitivity of a tissue is: proportional to the rate of proliferation of its cells, and/or inversely proportional to the degree of cell differentiation.

In general, actively proliferating cells are most sensitive to radiation. Thus, cellular radio-sensitivity tends to vary inversely with the degree of differentiation. Vegetative cells comprising of differentiated functional cells of a large variety of tissues are generally the most radio-sensitive. Examples include: free stem cells of haematopoietic tissue, cells deep in the intestinal crypts, primitive spermatogonia, granulosa cells of developing and mature ovarian follicles, basal germinal cells of the epidermis, germinal cells of the gastric glands, large and medium sized lymphocytes and mesenchymal cells.

Therefore, the most sensitive are blood forming cells, followed by skin, bone, teeth, muscle and nervous system. This also means that a developing embryo is most sensitive to radiation during the early stages of differentiation and an embryo/foetus is more sensitive to radiation exposure in the first trimester than in later trimesters of pregnancy.

Differentiating cells are somewhat less sensitive to radiation. The best examples of this type of cell are the dividing and differentiating cells of the granulocytic and erythrocytic series in the bone marrow, differentiated spermatogonia and spermatocytes in the seminiferous tubules and the ovocytes.

Totally differentiated cells are relatively radio-resistant. This class includes hepatocytes, cells of interstitial gland tissue of the gonads, smooth muscle cells, and vascular endothelial cells.

Fixed non-replicating cells are most radio-resistant. This group includes the long-lived neurons, striated muscle cells, short-lived polymorphonuclear granulocytes and erythrocytes, spermatids and spermatozoa, and the superficial epithelial cells of the alimentary tract.

Observed cellular effects of radiation, whether due to direct or indirect damage, are basically similar for different kinds and doses of ionising radiation.

Manifestations of Radiation Damage

This is dose dependant and the absorbed energy deposited. It is important to understand these concepts in diagnostic applications as one need to minimise cell damage as much as possible. For therapeutic applications, one needs to ensure cell death that is the predominant effect to be obtained.

One of the simplest effects to observe is *cell death,* the course of which can be described by various terms as described below:

Pyknosis: The nucleus becomes contracted, spheroidal, and filled with condensed chromatin.

Karyolysis: The nucleus swells and loses its chromatin.

Protoplasmic coagulation: Irreversible gelatin formation occurs in both the cytoplasm and nucleus.

Karyorrhexis: The nucleus becomes fragmented and scattered throughout the cell.

Cytolysis: Cells swell until they burst and then slowly disappear.

Non-lethal changes in *cellular function* can occur as a result of lower radiation doses. These include:

1. Delay in certain phases of the mitotic cycle. This inhibition occurs before prophase in the mitotic cycle, at a time disrupting cell growth, resulting in depletions of all populations.
2. Irradiated cells may show both increased and decreased permeability.
3. Changes in motility.

At a *molecular level* there is damage to enzymes, DNA and biological pathways. Damage to cell membranes, nucleus and chromosomes occur at a sub-cellular level. Cellular effects are observed as cell death, inhibition of cell division, and carcinogenesis.

Systemic disruption occurs at the tissue level and death with shortening of life is a manifestation of whole body radiation. If a population is involved there are genetic changes in individuals.

Radiation-Induced Chromosome Damage

Cell nuclei contain chromosomes which in turn contain the genes controlling cellular somatic and reproductive activity. These chromosomes are composed of DNA, the macromolecule containing the genetic information. This is a large, tightly coiled, double-stranded molecule, and is sensitive to radiation damage. Radiation effects range from:

- Complete breaks of the nucleotide chains of DNA;
- Point mutations which are essentially radiation induced chemical changes in the nucleotides which may not affect the integrity of the basic structure;
- Intermediate effects, such as abnormal bonding between adjacent molecules and alterations in viscosity resulting in translocations, trisomies, truncation and other abnormalities.

Genetic Effects

Laboratory studies in animals indicate increased mutation rates with small doses of radiation. As radiation dose increases, mutation induction also increases. *Mutations per unit dose decrease at low dose rates.* However, viable mutations are still extremely rare. Most of the mutations are lethal, and thus, self-limiting. It must be kept in mind that radiation doses increase natural mutation rates and that the mutations produced, and not visibly detected, are permanent in regard to future generations.

Bystander effects due to untargeted cells not hit by direct radiation, results from exposures to cells in the vicinity. The effects can lead to genomic instability, cell death, apoptosis, mutations, chromosomal aberrations and other cellular changes. At low doses bystander effects may be more important than targeted effects. Targeted effects are predominant in high dose exposures. This means that the effects are more

widespread in the surrounding tissues as well as in the tissues directly exposed to the ionising radiation due to the bystander phenomenon.

The transmission of damaging effects to the non-targeted tissues are by signals mediated via plasma and factors. The exact mechanism is yet to be proved.

CLINICAL MANIFESTATION OF RADIATION EFFECTS

Each of the numerous cell renewal systems making up an animal's total cellular mass is normally in an equilibrium state between cell formation, proliferation, maturation, and death. Some systems, such as the adult central nervous system in higher animals, are stabilised at the end-point of maturation, and the functional cells of such a system are not replaced if lost or destroyed. Other organ systems, such as the liver, which do not normally replace cells at a rapid rate, have the potential to regenerate large numbers of cells if needed. Other organ systems, such as the skin, the reproductive system, the gastrointestinal tract, and the haematopoietic system in the bone marrow, maintain a continuous high cell turnover rate. Bone marrow also has a large reserve capacity in the adult. A large fraction of it is normally non-functioning but has the potential to be functional if required. Failure of a particular organ system may or may not lead to death of the animal, depending on the importance of that system's functions, i.e. failure of gonadal function would not be lethal, whereas failure of bone-marrow function would be.

Acute Radiation Syndrome (ARS)

Acute exposure of a person to moderate to high dose of radiation can lead to mild symptoms of nausea, vomiting to severe symptoms leading to immediate death (**Table 1**).

Table 1: Dose and Effects of Radiation Syndrome

Dose	Effect
<50 rads (0.5 Gys)	Generally no clinical effect; subject asymptomatic
50 to 100 rads (0.5 to 1 Gys)	Mild nausea; WBCs increased and then decreased
100 to 200 rads (1 to 2 Gys)	Nausea, vomiting, fatigue; WBCs increased and then decreased; recovery in 2 to 4 days
200 to 400 rads (2 to 4 Gys)	2 to 3 days of nausea, vomiting, fatigue; WBCs markedly decrease, platelets decrease; epilation, diarrhoea, bleeding; recovery in 1 to 3 weeks; death occurs in 4 to 6 weeks
300 to 500 rads (3 to 5 Gys)	LD 50; dose lethal to 50% of persons exposed
400 to 600 rads (Gys)	Severe nausea, vomiting, diarrhoea and sore throat; WBCs very low, platelets very low; recovery period brief or absent; symptoms recur with bleeding and diarrhoea; death occurs in less than 30 days
600 to 1,000 rads (6 to 10 Gys)	Severe and continuous nausea, diarrhoea, and vomiting; death occurs in 1 to 10 days
>1,000 rads (>10 Gys)	Severe illness, disorientation, ataxia, burning sensation and shock; death occurs in 10 to 36 hours

Lethality (LD_{50})

When comparing the effects of various types or circumstances, that dose which is lethal to 50% of a given population is a very useful parameter. The term is usually defined for a specific time, being limited, generally, to studies of acute lethality. The common time periods used are 60 days for large animals and humans. Medically, other figures of interest are the dose that will kill virtually noone, (LD5), and the dose that will kill virtually everyone (LD95). Approximations of those doses are within the ranges 200 to 300 cGy (free in air) and 600 to 700 cGy (free in air), respectively.

Recovery Processes

Understanding the process of recovery from radiation damage is necessary in determining the protocols for radiation therapy. If there is time between therapy fractions and repair takes place, effective results will not be seen.

A variety of recovery processes may reduce radiation damage to a varying extent. For example, when a chromosome is broken, the broken ends tend to rejoin, thus reconstituting the chromosome, but occasionally the broken ends seal over before rejoining, thus leaving permanent chromosome damage. If two (or more) chromosomes are broken within the same cell, rejoining of inappropriate broken ends can occur and it may lead to permanent chromosomal change of a different kind. Repair of the broken ends of chromosomes, like all other repair processes following radiation damage, is not specific in respect of radiation damage.

Intra-cellular repair occurs when individual irradiated cells have the ability to repair themselves as long as the amount of intra-cellular damage does not exceed a threshold value.

Repopulation brought about by stem cell proliferation is a particularly important recovery mechanism in both the bone marrow and the gastrointestinal tract whenever the radiation exposure has been large enough.

Repair is a biological process specific to a particular kind of damage which comes into play whatever the agent which causes that damage. The third, a combination of the first two types of recovery, can be very approximately quantified for lethality in humans by the use of the operational equivalent dose formula in cases where the irradiation period is protracted over several hours or longer.

Delayed Effects

The above description is often the early effects of radiation. However, radiation effects can manifest several years later. Hence, it is important to ensure, when radiation of any form is used in the diagnostic and therapeutic management, the awareness of patients about the consequences which might occur many years later. The risk factors for a particular type of manifestation of delayed effects of radiation should be kept in mind when exposing a patient to radiation.

The present increase in the life span of persons all over the world can be a hazard for the development of higher incidences of delayed radiation effects.

General

Late or delayed effects of radiation occur following a wide range of doses and dose rates. Delayed effects may appear months to years after irradiation and include a wide variety of effects involving almost all tissues or organs. Some of the possible delayed consequences of radiation injury are: life shortening, carcinogenesis, cataract formation, chronic radiodermatitis, decreased fertility, and genetic mutations.

Carcinogenesis

Irradiation of almost any part of the body increases the probability of cancer. The type formed depends on such factors as area irradiated, radiation dose, age, and species. Irradiation may either increase the absolute incidence of cancer or accelerate the time or onset of cancer appearance, or both. There is a latent period between the exposure and the clinical appearance of the cancer. In the case of the various radiation-induced cancers seen in mankind, the latency period may be several years. Latent periods for induction of skin cancers in people have ranged from 12 to 56 years after X-ray irradiation. Fifteen years is reported as a latent period for bone tumours from radium.

A leukeamogenic effect was expected and found among Hiroshima and Nagasaki survivors. Peak incidence occurred 6 years after exposure and was less marked for chronic granulocytic leukaemia than acute leukaemia. The incidence was inversely related to distance from the hypocentre.

British persons receiving radiotherapy for spondylitis showed a dose response relationship for leukaemia, with peak incidence occurring 5 years after the first exposure. Studies have demonstrated that ionising radiation can induce more than one kind of leukaemia in people, but not chronic lymphocytic leukaemia.

Predisposing factors for tumour development include heredity, age, hormones, and prior exposure to physical trauma, chemical agents and ionising radiation. The actual processes by which cancer is induced are not known. Somatic mutations, virus infections, and precancerous abnormalities in tissue organisation and vascular supply have all been postulated.

Cataract formation

A late effect of eye irradiation is cataract formation. It may begin anywhere from 6 months to several years after exposure. While all types of ionising radiation may induce cataract formation, neutron irradiation is especially effective in its formation, even at relatively low doses. Cataract formation begins at the posterior pole of the lens and continues until the entire lens has been affected. The threshold for detectable cataract formation in 2 Sv (sievert) [200 rem (Roentgen equivalent, man)] for acute radiation doses and 15 Sv (1500 rem) for protracted doses.

Chronic radiodermatitis

Delayed, irreversible changes of the skin usually do not develop as a result of sub-lethal whole-body irradiation, but instead follow higher doses limited to the skin. These changes are common complications in radiation therapy. Erythema occurs at low doses ranging from 60 to 80 Sv followed by skin necrosis and ulceration at higher doses. Chronic exposure over 20 Sv can lead to dermatitis with skin cancers.

Genetic or heritable effects

Genetic or heritable effects appear in the future generations of the exposed person as a result of radiation damage to the reproductive cells. They have been extensively studied in plants and animals, but risks for genetic effects in humans are seen to be considerably smaller than the risks for somatic effects. Therefore, the measures used to protect the exposed person from harm are equally effective to protect future generations from harm.

Genetically significant dose (GSD) is that dose if received by any member of the population which would be expected to produce the same number of genetic abnormalities as are produced by the actual doses received in various individuals. GSD for natural background is 3.6 mSv per year, medical exposures is 0.4 mSv and nuclear medicine procedures is 0.14 mSv.

Dose and Effect

Stochastic effects: These effects have no threshold and the severity of the effect does not vary with the dose. The probability of occurrence, however, increases as the dose increases. Cancer is a stochastic effect, particularly leukaemia which has a latent period of 2 to 10 years post exposure. The risk for leukaemia is significantly increased above acute doses of 40 rads (0.4 Gy). There is a longer latent period for solid tumours (10 to 40 years), such as squamous cell carcinoma of the skin and adenocarcinoma of the breast or lung. There may be some associated increased risk for childhood cancer following exposure in utero. Genetic effects are also considered under this category.

Non-stochastic effects or deterministic effects: The severity of the effect varies with the dose and the effects are not seen below a certain threshold level of radiation. A minimum dose of 200 rem (2 Sv) is required for the development of cataracts. The threshold for developing a vision impairing cataract under conditions of prolonged, fractionated exposure is felt to be 800 rem. Temporary sterility in males can be seen following acute doses of 15 rem (0.15 Sv), while permanent sterility can be seen after doses of 350 rem (3.5 Sv). In females, permanent sterility can be seen following doses of 250 to 600 rem (2.5 to 6.0 Sv).

Dose response curve

It is believed that at low dose rates, defence mechanisms in the cells can operate to repair some of the damage caused by radiation. In this region of low dose, the effect (i.e. the probability of producing cancerous cells) is thought to be proportional to the dose. At higher dose rates, greater than 100 mGy per hour, two or more ionising events might occur in the critical parts of cells before the repair mechanism would have a chance to operate. At this point, the slope of the dose-effect curve increases and the effect will depend on the square of the dose, D2, rather than just on D (**Figure 1**).

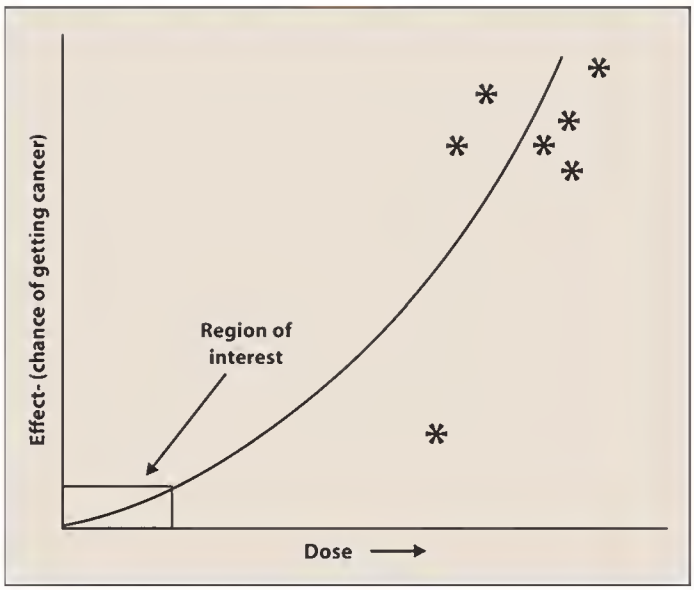

Figure 1: The dose effect curve showing exponential increase in cancer risk with high dose radiation.

This means that if the whole body is exposed to 1 Sv of ionising radiation, an extra 4% chance of contracting a cancer that will be fatal many years after the exposure. The word 'extra' is used because one normally has a 20% to 25% chance of dying from cancer.

Other stochastic effects also occur. Radiation can cause changes in DNA, the 'blueprints' that ensure cell repair and replacement produces a perfect copy of the original cell. Changes in DNA are called mutations.

Sometimes the body fails to repair these mutations or even creates mutations during repair. The mutations can be teratogenic or genetic. Teratogenic mutations are caused by exposure of the foetus in the uterus and affect only the individual who was exposed. Genetic mutations are passed on to offsprings.

Potential Effects of In Utero Exposure

Prenatal death occurs if the radiation is received during perimplantation. The most sensitive period for neonatal death to occur following radiation exposure is between 3 to 5 weeks of gestation. The most sensitive period for congenital abnormalities is during the period of organogenesis. Growth retardation can also be seen in irradiated foetuses. Long-term effects of the radiation include sterility, genetic effects, induction of malignancies, and neurologic impairment.

Mental retardation: Mental retardation can be seen following in-utero radiation exposure and is the most commonly documented abnormality in humans who are prenatally exposed. The foetus is most susceptible to radiation delivered during the 8 to 15 week period, and somewhat less susceptible between 16 and 25 weeks. The risk of mental retardation is dose related and is only about 4% for a 10 rem (0.1 Sv) dose, while it may be as high as 43% for a 100 rem (1 Sv) dose. There may be a threshold for retardation between 20 and 40 rem (0.2 to 0.4 Sv), but this has not yet been proven.

Malignancy: The increased risk of cancer in the foetus is estimated to be approximately 500 deaths before the age of 10 years among 1 million children exposed shortly before birth to 1 rad [2 x 10 (to the –4) per rad]. The leukaemia risk for the child is greatest if radiation was received during the first trimester.

Considerations for Pregnancy Termination

1. Threshold dose for developmental effects approximately 0.1 Gy.
2. Normal rate of preclinical loss >30%. At 0.1 Gy, increase of 0.1% to 1%.
3. The foetal absorbed dose >0.5 Gy at 7 to 13 weeks: substantial risk of IUGR and central nervous system damage.
4. 0.25 to 0.5 Gy at 7 to 13 weeks: parental decision with physician's guidance.

MINIMISING HEALTH EFFECTS OF IONISING RADIATION

Life style abnormalities, natural disasters and accidents are greater risk factors than exposure to small amounts of radiation as encountered in medical exposures and in radiation workers.

Some scientists assert that low levels of radiation are beneficial to health (this idea is known as hormesis).

Although exposure to ionising radiation carries a risk, it is impossible to completely avoid exposure. Radiation has always been present in the environment and in our bodies. However, we can avoid exposure. Although one cannot sense ionising radiation, there is a range of simple, sensitive instruments capable of detecting small amounts of radiation from natural and man-made sources.

1. *Dosimeters:* These can measure an absolute dose received over a period of time. The TLDs are normally used to obtain your official dose of record. TLDs are processed routinely at the end of each calendar quarter. TLDs are sensitive to beta, gamma, and neutron radiation.
2. *Self reading pocket dosimeters (SRPDs):* The term SRPDs applies to a variety of devices which can be read by the wearer to determine the dose received. SRPDs are used as supplemental devices to aid in dose tracking during activities where elevated doses are possible.
3. *Pocket ion chambers (PIC):* These are small instruments which operate on the principle electroscope. Typically, the range of the PIC is 0 to 200 mR. This is one of the most common supplemental dosimeters used in radiation areas.
4. *Electronic dosimeters (ED):* These are sometimes used instead of and in addition to PICs when it is helpful to have additional capability of dose or dose rate alarm functions.
5. *Geiger counters and scintillometers:* These measure the dose rate of ionising radiation directly.
6. *Film badge dosimeters:* These enclose a photographic film which will get exposed to radiation.

In addition, there are 3 ways for personal protection:

1. *Time:* Limiting or minimising the exposure time to reduce the dose.
2. *Distance:* The intensity of exposure reduces as a square of the distance from the source.
3. *Shielding:* Barriers of lead, concrete or water are protective against radiation, such as gamma and neutrons. That is why certain radioactive materials are stored or handled under water or by remote control in rooms constructed of thick concrete or lined with lead. There are special plastic sheets for stopping beta rays and air will stop alpha particles.

It should be noted that the setting of a dose limit is equivalent to specifying a maximum acceptable level of risk. It is not acceptable to be exposed to the full extent of the limit if a lower dose can be reasonably achieved. The average dose received by an occupationally exposed worker is less than 0.2 mSv per year.

27.11 Environmental Disasters

ME Yeolekar, Milind Y Nadkar

Emergency management is the discipline that involves preparing for disaster before it occurs, disaster response (e.g. emergency evacuation, quarantine, mass decontamination, etc.), and rebuilding society after natural or human-made disasters have occurred. In general, any emergency management is the continuous process to manage hazards in an effort to avoid or ameliorate the impact of disasters. Effective emergency management relies on integration of emergency plans at all levels of government and non-government involvement.

PHASES IN EMERGENCY MANAGEMENT

Mitigation

Mitigation efforts attempt to prevent hazards from developing into disasters altogether, or to reduce the effects of disasters when they occur. The mitigation phase differs from the other phases because it focuses on long-term measures for reducing or eliminating risk. Mitigation is the most cost-efficient method for reducing the impact of hazards; however it is not always feasible.

Preparedness

Preparedness is a continuous cycle of planning, organising, training, equipping, exercising, evaluation and improvement activities. It ensures effective coordination and the enhancement of capabilities to deal with natural disasters, acts of terrorism, and other man-made disasters.

Response

This phase includes the mobilisation of the necessary emergency services and first responders in the disaster area.

Recovery

The recovery phase aims at restoring the affected area to its normal state. The focus of this phase is different from response phase; recovery efforts are started after immediate needs are addressed.

EMERGENCY MANAGEMENT IN INDIA

National Disaster Management Authority of India, a government agency under the Ministry of Home Affairs is India's Institutional Mechanism for effective disaster management. In recent years, there has been a shift in emphasis from response and recovery to strategic risk management and reduction. There is more emphasis on community participation rather than a government-centred approach with network of Emergency Response Centres and Crisis Management Group and strengthening the Institutional Frameworks for regulatory.

Efforts involve the provision of emergency management training for first responders, the creation of a single emergency telephone number, and the establishment of standards for EMS staff, equipment and training.

TRIAGE

Triage means to sort. When there is sudden flux of patients in emergency room or at the site of disaster one needs to prioritise which patients need treatment earlier than others. Triage is essential in medical emergencies, including the pre-hospital setting, disasters, and during emergency room treatment.

Types of Triage

Simple triage

Simple triage is usually used in a scene of a mass-casualty incident. It helps to sort patients into those who need critical attention and immediate transport to the hospital and those with less serious injuries. This triage can be started before transportation becomes available.

Simple triage and rapid treatment (START)

START is a simple triage system that can be performed by lightly-trained lay and emergency personnel in emergencies. It does not intend to supersede or instruct medical personnel or techniques. Colour codes (flags) are attached to patients for identification and management. Triage separates the injured into four groups:

- The deceased who are beyond help (Black).
- The injured who can be helped by immediate transportation (Red).
- The injured whose transport can be delayed (Yellow).
- Those with minor injuries, who need helpless urgently (Green).

Advanced triage

In advanced triage, doctors decide that some serious patients should not receive advanced care because they are unlikely to survive. Advanced care will be used on patients with less severe injuries. However, advanced triage has ethical implications. It is used to divert scarce resources away from patients with little chance of survival in order to increase the chances of survival of others who are more likely to survive.

ENVIRONMENTAL DISASTER

An environmental disaster is a disaster that is due to human activity and should not be confused with natural disasters; but forced human movement, as in Haiti, can cause cholera, after flooding from hurricane. Industrialisation all over the world has introduced several chemicals in the environment causing exposure to wide variety of toxic agents for the people living in such environment. The respiratory tract tends to bear the maximum brunt of such exposure leading to upper and lower respiratory tract inflammation. The upper respiratory tract through the anatomical structures like nasal turbinates and the cough reflex usually removes maximum amount of toxic gases inhaled. The dose reaching into the lower respiratory tract however is cumulative and produces long-term inflammation due to impairment of mucociliary clearance and alveolar macrophage defence.

General Mechanism of Injury Due to Toxic Chemicals

Massive acute exposure leads to inhalation of irritant gases resulting in acute inflammatory reaction in the respiratory mucosa mainly in the form of capillary damage and oedema, and severity of damage essentially depends on concentration of gas in the environment, solubility in water and duration of the exposure.The inflammatory reaction produced by noxious gases is similar for almost all agents but the severity differs depending on the above mentioned factors.It can range from mild respiratory inflammation to alveolar oedema, shock and disseminated intravascular coagulation (DIC) syndrome—the last one accounting for most of the fatalities in inhalational disasters.

Following are two examples of large scale disasters due to environmental accidents.

The gas leak in Bhopal (MP), 1984, the union carbide gas leak

December 3, 1984 has become a memorable day for the city of Bhopal in Madhya Pradesh, India. Shortly after midnight, a poisonous gas cloud escaped from the Union Carbide India Limited (UCIL) pesticide factory. The cloud of poisonous gas containing 15 metric tons of methyl isocyanate (MIC) escaped from the factory covering an area of more than 30 square miles. The casualty was four thousand and many more suffer from chronic disease consequential to gas exposure, today. This incident happens to be one of the worst known industrial environmental disasters.

Chernobyl: Russian nuclear power plant explosion (1986)

Reactor stress at nuclear power plant in Ukraine resulted in ten times increase in energy production than the normal level and finally culminated into explosion by the escaped steam and formation of an atmospheric cloud containing approximately 185 to 250 million curies of radioactive material caused fire instantly killing 31 people. Immediate aftermath of the earthquake and Tsunami in Japan, March 2011 was the melting of fuel rods in the nuclear reactors causing nuclear blast radiation disaster. Graded response to nuclear/radiologic emergencies has become necessary. Growing concern over ocean contamination.

Radiation

It is naturally present in our environment and has been since the birth of this planet. Life has evolved in an environment, which has significant levels of ionising radiation. It comes from outer space (cosmic) and the ground (terrestrial). The average annual radiation exposure from natural sources is about 300 millirem (3 millisieverts). In addition, man-made sources of radiation from medical, commercial and industrial activities contribute another 60 mrem (0.6 mSv) to our annual radiation exposure. One of the largest of these sources of exposure is medical X-rays. Diagnostic medical procedures account for about 40 mrem (0.4 mSv) each year.

Biological effects of radiation

Biological effects of radiation on living cells may result in three outcomes; firstly, injured or damaged cells repair themselves, resulting in no residual damage; secondly, cells die, much like millions of body cells do everyday, being replaced through normal biological processes; and thirdly, cells incorrectly repair themselves resulting in a biophysical change.

Ammonia

It is mostly used in fertilisers, as a solvent in textile, leather, paper, and pulp industries and also in petroleum refining processes and cold storage. Exposure occurs mostly in the setting of an industrial accident. Toxicity depends on duration of exposure. It usually gets dissolved in moisture present in eyes, oral cavities, pharynx, and lungs and gets converted into ammonium hydroxide which is responsible for its corrosive action. Patients usually present with headache, salivation, swelling around eyes and lips, lacrimation, blurred vision, corneal opacification with scarring if head and face are involved. Cough, dyspnoea, bronchospasm, and consolidation occur when lungs are involved. Abdominal pain and severe vomiting leads to shock in patients with gastrointestinal tract involvement. Skin manifestations include erythema, oedema, blisters and vesicle formation. Treatment is to remove the patient from environment, if skin exposure occurs wash the whole body thoroughly with water. Administration of intravenous fluid becomes necessary in those with severe vomiting and hypovolaemia. Corticosteroids can be used during acute exposure along with antibiotics. Ventilatory support may be required in some cases.

Sulphur Dioxide

See Chapter 3 on Section 27 Environmental Medicine.

Carbon Monoxide

Carbon monoxide is a colourless, odourless gas formed when substances containing carbon are burnt with an insufficient supply of air. The combustion of fuels such as petrol, gas, coal and wood generate emissions of carbon monoxide. Motor vehicles are the main source of in urban areas. Exhaust emissions contain carbon monoxide from incomplete burning of fuel in the engine. Carbon monoxide can have serious health impact on humans. When inhaled, the carbon monoxide binds to the haemoglobin in the blood (and becomes carboxyhaemoglobin) in place of oxygen and is carried through the blood stream. This reduces the oxygen-carrying capacity of the red blood cells and decreases the supply of oxygen to tissues and organs, especially the heart and brain. This can be a serious problem for people with cardiovascular disease. Most people in the community need to be exposed to a level of 200 ppm for several hours before they start to feel effects. Carboxyhaemoglobin formation is reversible when the person is no longer exposed to carbon monoxide.

Treatment

The treatment for carbon monoxide poisoning is to immediately remove the victim from the exposure without endangering oneself. The main medical treatment for carbon monoxide poisoning is 100% oxygen by a tight-fitting oxygen mask. Oxygen hastens the dissociation of carbon monoxide from haemoglobin, improving tissue oxygenation by reducing its biological half-life. Hyperbaric oxygen is also used in the treatment of CO poisoning; hyperbaric oxygen also increases carboxyhaemoglobin dissociation and does so to a greater extent than normal oxygen. Hyperbaric oxygen may also facilitate the dissociation of CO from cytochrome oxidase. Further specific treatment for other complications such as seizure, cardiac abnormalities, pulmonary oedema, and acidosis may be required. Late development of neuropsychiatric impairment is one of the most serious complications of

poisoning. Prevention remains a vital public health issue, requiring public education on the safe operation of appliances, heaters, fireplaces, and internal-combustion engines, as well as increased emphasis on the installation of carbon monoxide detectors.

Chlorine

Chlorine is a halogen element used as a reagent in plastic manufacturing and paper industries and also used in drinking water and swimming pool water to kill harmful bacteria. It is also used as part of the sanitation process for industrial waste and sewage. Chlorine gas can be pressurised and cooled to change it into a liquid so that it can be shipped and stored. When liquid chlorine is released, it quickly turns into a gas that stays close to the ground and spreads rapidly. Chlorine gas can be recognised by its pungent, irritating odour, which is like the odour of bleach. The strong smell may provide an adequate warning to people that they have been exposed. The gas appears to be yellow-green in colour. Chlorine itself is not flammable, but it can react explosively or form explosive compounds with other chemicals such as turpentine and ammonia. Mechanism of toxicity is the generation of hypochlorous acid, hydrochloric acid and chloramine gas which is formed when ammonia and bleach are mixed. These by-products cause coagulative necrosis and oxidative damage. Symptoms of respiratory tract usually predominate after chlorine exposure. During or immediately after exposure to dangerous concentrations of chlorine, the following signs and symptoms may develop like cough, chest tightness, burning sensation in the nose, throat, and eyes, watery eyes, blurred vision, nausea and vomiting. Burning pain, redness, and blisters appear on the skin if exposed to chlorine gas. Difficulty in breathing may appear immediately if high concentrations of chlorine gas are inhaled, or may be delayed if low concentrations of chlorine gas are inhaled. Pulmonary oedema occurs on severe exposure. Management usually involves leaving the area where the chlorine was released and getting to fresh air. Remove clothing and rapidly wash entire body with soap and water, and get medical care as quickly as possible. Treatment is largely supportive as no antidote for chlorine is available.

Nitrogen Dioxide

Exposure to oxides of nitrogen occurs in welders using acetylene torches, coal miners, chemical industries manufacturing dyes, farmers who work with silage when it is called as silo fillers disease, smoke from cigarettes, cigar pipes and diesel fumes. Nitrate concentration is increased in grain plants by the use of fertilisers. Nitrates combine with organic acid to form nitrous acid which in turn decomposes to nitrous oxide (N_2O), nitrogen tetraoxide (N_2O_4) and nitrogen penta oxide (N_2O_5). N_2O and N_2O_4 are responsible for injury to lungs. The threshold limit of nitrous oxide is 5 ppm, and humans exposed to even to 50 ppm for short duration are also at risk of developing acute lung injury. Nitrogen dioxide is a powerful oxidant and is capable of causing extensive damage to respiratory epithelial cells. Clinical course can be divided into following stages:

Super acute stage: This phase follows immediately after exposure. Patients suffer severe hypoxia and formation of methaemoglobin. Most are critically ill and may succumb before medical aid can be made available.

Acute phase: Exposed person exhibits dyspnoea, nausea, headache, tachycardia, and weakness, and may complain of pleuritic chest pain. These symptoms develop after a lag-period of few hours. Bronchospasm appears in most cases and pulmonary oedema in few.

Subacute and chronic phase: Pulmonary oedema clears in few days and patient passes into an asymptomatic phase lasting for 2 to 5 weeks. The X-ray of chest appears normal and the patient may have mild dyspnoea. After 3 to 6 weeks there is a relapse of symptoms and the patient develops progressive dyspnoea, cough, and cyanosis. Chest X-ray shows multiple, discrete, nodular opacities. In severe cases, hypoxia and CO_2 retention may be fatal.

The treatment is mainly supportive. Methaemoglobinaemia, if present, should be treated with IV methylene blue. Corticosteroids may be helpful in some cases.

Ozone

See Chapter 3 of Section 27 Environmental Medicine.

Isocyanates

These compounds are used in paint, furniture, rubber and pesticide industry. Commonly used isocyanates are toluene diisocyanate (TDI), methylene diphenyl diisocyanate (MDI), naphthalene diisocyanate (NDI), hexamethylene diisocyanate (HDI). These compounds cause pulmonary and skin manifestations. Pulmonary manifestations are mainly due to bronchoconstriction and may lead to toxic bronchitis and asthma, accelerated decline in FEV1 and extrinsic alveolitis. Skin manifestations range from localised itching to widespread eczema. Treatment is symptomatic.

Phosgene

It is a colourless gas heavier than air with a musty odour resembling mown hay, commonly used in pesticide industry. On exposure it produces irritation with coughing and sense of suffocation. Large exposure can cause increased capillary permeability resulting in large shifts in body fluids and shock with pulmonary oedema. Marked bronchiolar and bronchial congestion occurs early and emphysematous lesions may occur as delayed sequelae.

General Treatment

Treatment of all noxious gas exposure is similar as basic mechanism is identical for many of them. Prime importance should be given to maintenance of airway and circulation. As per requirement continuous positive airway pressure (CPAP) and intermittent positive airway pressure (IPPV) should be provided. Antibiotics should be used only if infection is suspected, otherwise prophylactic antibiotics have no role. Corticosteroids are recommended in acute phase to prevent bronchiolitis. Methylprednisolone 1 gm every 12 hourly can be used for three days.

28.1 Geriatric Medicine

Vinod Kumar

DEFINITION AND EPIDEMIOLOGY

Geriatric medicine is the specialised branch of medicine that deals with medical problems of older persons. United Nations term older persons as those aged 60 years or above and in India also, cut off point is 60 years. This cut off point is purely arbitrary and does not necessarily indicate the onset of ageing process or age-related disorders in an individual. In fact, older persons are highly heterogenous, lot showing great variations in age-related physiological decline and age-related disorders. Generally, age-related decline in strength, vision, memory, locomotion, nutrition, immunity and homeostasis develop slowly while onset of disease may be abrupt.

There is a steady increase in the ageing of our population and therefore geriatric medicine has to be established in our country while it is well-established in other countries. Demographic trends reveal that population of older persons is growing faster than that of general population. Since 1950, life expectancy in India at birth has almost doubled from 32 years to 65 years. Total Indian population was 350 million in 1950, 1112 million in 2006 and this is projected to be 1572 million in 2050, i.e. a percentage increase of 40% in a matter of 44 years. In contrast, population of older persons (60+) which was 19 million in 1950 and 90 million in 2006 will be 330 million in 2050, thus showing a much greater increase (270%). Moreover, amongst them, the older ones (above 80 years) are growing at a fast pace. Their population which is 0.8 million in 1950, 9 million in 2006 which is projected to be 53 million in 2050, i.e. a rise of almost 500%. These very elderly people are usually weaker, more frail, insecure and dependent, and suffer more often from age-related diseases, neglect and abuse as compared to young olds (60 to 79).

GERIATRIC MEDICINE VERSUS GENERAL MEDICINE

Older persons frequently suffer from multiple disorders, require long-term treatment with multiple drugs and may often need physical and rehabilitative therapy for various residual disabilities. Some diseases occur more often and some occur almost exclusively in older persons. Degenerative disorders like cardiovascular disease, chronic obstructive pulmonary disease, diabetes, osteoarthritis and infection-related disorders like pneumonias, urinary tract and other infections occur more frequently in older persons while diseases such as Alzheimer's disease, prostatic hypertrophy, postmenopausal osteoporosis, and macular degeneration occur almost exclusively in old age. Clinical presentation of many disorders in old age may be atypical and different. In old age, myocardial infarction may occur without chest pain, infection may be without fever and hypertension may be without a rise in diastolic pressure. Obstructive jaundice in older person is more likely to be of malignant origin. Bacteriuria, impaired glucose tolerance and premature ventricular contractions do not have the same degree of prognostic gravity as in younger subjects. An older person is more vulnerable to confusion or drowsiness in response to an acute event compared to young person. Thus, approach to a geriatric patient should be different. Developing a rapport with an older patient, art of history taking and of being a patient listener, assessing him comprehensively and ordering only limited but necessary investigations, are some of the requisites of a geriatric physician.

CLINICAL ISSUES IN GERIATRIC PRACTICE

Older persons seek medical advice more than any other segment of adult population. In a developing country like India, where demographic transition has occurred faster, but public hygiene has remained inadequate, older persons often suffer from double burden of diseases, i.e. both degenerative and infection-related diseases. Consequently, increasing number of people surviving longer into old age suffer from type 2 diabetes, coronary heart disease, hypertension, stroke, chronic obstructive pulmonary disease, Alzheimer's disease, osteoarthritis, osteoporosis, prostatic hypertrophy, cataracts, macular degeneration, and cancer, etc. and at the same time they are vulnerable to infections involving respiratory (including TB), urinary and digestive tract. Acute infections may present atypically with absence of fever and leucocytosis; instead, they may present with impaired intellect/memory, incontinence, instability or immobility—the so called 'geriatric giants'. Malnutrition, occult hypothyroidism, renal injury, depression, urinary incontinence and sexual problems are also common in old age. For a detailed description of geriatric disorders, reader is referred to consult a 'Textbook of Geriatrics'. Following description highlights some of the important diseases in old age.

The Frail Older Person and the Frailty Syndrome

Older persons who become physically weak, tired, underweight, and unable to easily walk are termed as frail. They have reduced physiological reserve and are unable to carry out activities of daily living in stressful situations. They are often 80+ and may get disabled by falls, infections, drug reactions or bereavements. When frail individuals have several impairments like undernutrition, osteoporosis, muscle loss, neuronal loss, it is then termed as frailty syndrome. Frail subjects are prone to falls and fractures. Undernutrition is brought about by reduced appetite and taste, bowel dysfunction, and physical inactivity in old age while hormonal factors and calcium/vitamin D deficiency additionally contribute to osteoporosis. Muscle loss or sarcopaenia in old age is due to reduced protein intake, sedentarism, diabetes, and atherosclerosis. Hormonal deficiency also leads to frailty. Gradual neuronal loss and cognitive impairment occurs in many frail older persons. Prevention and treatment of frailty syndrome includes physical activity, adequate protein, calcium and vitamin intake, use of ACE inhibitors and hormone replacement therapy together with control of underlying disorders.

Osteoporosis

Ageing is associated with progressive bone loss and osteoporosis with increased risk of hip and other fractures. It is more prominent

in menopausal women due to cessation of oestrogen secretion. Risk factors for osteoporosis fractures include female sex, advancing age, small built, calcium and vitamin deficiency, sedentarism, smoking, alcoholism and caffeine excess. Diagnosis is made by measuring bone mineral density (BMD) by dual energy X-ray absorptiometry (DEXA) which is also useful in predicting fractures and monitoring of therapy. Detection in asymptomatic stage and prevention of fractures is important. Preventive methods include adequate intake of calcium (1,200 mg/dL) and vitamin D (400 to 800 IU/dL), walking and antigravity weight bearing/muscle strengthening exercises, fall prevention, smoking cessation and avoidance of alcohol intake. Sunlight exposure for at least 15 minutes a day for 3 times a week is good source of vitamin D. Hormone therapy for osteoporosis has now been largely replaced by use of safer drugs like bisphosphonates (alendronate, risedronate, ibandronate, pamidronate, zandronate), selective oestrogen receptor modulators, the SERMs (raloxifen, tamoxifen), calcitonin and teriparatide.

Falls in Older Persons

Falls are common in old age due to various diseases and are contributed by changes that occur with ageing. Balanced and upright posture in humans is maintained by central structures of cortex, sub-cortex and cerebellum which co-ordinate the sensory inputs from visual, vestibular and proprioceptive organs and by muscular activity, especially of the lower limbs. With ageing, physiological changes occur in the nervous system like impairment of vision and hearing, reduction of proprioceptive and vibratory sensations, increased sway, altered gait and poor positional control predispose to falls.

Falls best defined as sudden unintentional change in position causing a subject to land on ground or on lower level constitute a common problem in older persons. Recurrent falls mean two or more falls in six months. Risk factors are advancing age, female sex, cognitive and sensory impairment, polypharmacy and poor psychosocial and environmental factors. Falls may cause mild, moderate or severe bodily injury and even fractures and subdural haematoma. More than 80% of hip fractures in older persons are due to falls. Causes of falls are multiple. Drugs and even an unrelated acute event like pneumonia or dyselectrolytaemia can manifest as fall. An easy way for students to remember common causes of falls is to recall the words FALL SINDROME in which I replaces Y in the word syndrome (**Table 1**).

Table 1: Causes of Falls

F	Falls from extrinsic causes – uneven floors, defective staircases, footwear and poor lighting
A	Arrhythmias
L	Lower limb Neuropathy
L	Lower limb diseases like Osteoarthritis, Foot calluses, Bunions, and Hammer toes
S	Syncope – Aortic stenosis, Heart block, Mitral prolapse, Obstructive Cardiomyopathy
I	Instability
N	Neurological diseases – Vertebro-Basilar Insufficiency, Hemiplegia, Pakinsonism
D	Defects of Cognition, Vision and Hearing
R	Recurrent falls
O	Orthostatic hypotension and Orthopaedic problems of old age
M	Muscle weakness, especially of the lower limbs
E	Epilepsy and Seizures

A thorough history of the patient and family members, systemic clinical examination to identify various diseases and their relationship to falls and relevant investigations are essential. Assessment of cognition, muscle strength, postural stability, proprioceptive sensation and balance should be carefully carried out. Treatment of older persons presenting with falls include management of injury and associated illnesses, if any. Specific treatment depends on the underlying condition. Regular exercise and use of limbs are imperative. Interventions to improve strength, balance and endurance are also important.

Dementia

This is a clinical syndrome characterised by a decline in cognitive, intellectual and memory function due to disease process affecting the central nervous system. There is difficulty in many functions like problem solving, judgement, abstract thinking, geographic orientation, etc. There is no loss of consciousness and hence it is different from delirium. Minor memory lapses, such as forgetting one's keys or forgetting names do not ordinarily mean dementia. However, if one gets lost in familiar surroundings or fails to recognise spouse, diagnosis of dementia can be considered. Dementia is detected by the use of criteria of the diagnostic and statistical manual of mental disorders (DSM IV). Many diseases can result in dementia. Commonest are Alzheimer's disease (AD), a progressive and irreversible cause of dementia and the multi-infarct dementia (MID) also known as vascular dementia. Other causes of dementia are subdural haematoma, normal pressure hydrocephalus, hypothyroidism, head trauma, alcoholism, brain tumour and vitamin B12 deficiency, many of which are reversible with treatment.

Generalised neuronal loss in the cortex is the main histological change seen in cases of dementia. There is diffuse cerebral atrophy accompanied by enlargement of third and lateral ventricles. Atrophy of hippocampus is prominent. Senile plaques and neurofibrillary tangles (NFT) characterise AD. Plaques are extracellular lesions and are scattered throughout the cerebral cortex and hippocampus. They consist of beta amyloid. NFTs are in the nerve cell cytoplasm and contain tau proteins.

Clinical features include slow onset of forgetfulness, loss of interest in surroundings, impairment in social skills and personality. Depression may occur in early stages. Disorientation in time and space later followed by language impairment, aphasia, apraxia fits and paralysis are common. Finally, patient may start vegetating and death may ensue by intercurrent infection. Diagnosis of AD is supported by any of the neuro-imaging modalities like CT scan, magnetic resonance imaging (MRI), positron emission tomography (PET), single photon emission computed tomography (SPECT) and by ruling out other causes of dementia. Unless a dementia is due to treatable cause, management depends more on care of the patient rather than by curative methods. This is most applicable to AD. Advice to family and social support are key actions of treatment, drugs are practically of no value. Neuroprotectives, N-methyl-D-aspartic acid (NMDA) antagonists, anti-inflammatory agents and cholinesterase inhibitors like tacrine, donepzil, rivastigmine and galantamine are claimed to have beneficial effects on cognitive functions. Ancillary treatment includes alprazolam for disturbed sleep, anti-psychotics for restlessness and haloperidol for emotional stability.

Urinary Incontinence

It is involuntary passage of urine through urethral orifice, a common problem in older persons and a common cause of hospitalisation. It is commoner in females. It contributes to pressure sore, urinary tract infection and depression. Risk factors include smoking, chronic cough, depression, obesity, multiparity, oestrogen depletion and constipation. Apart from sanitation problems and interference in daily life, severe cases of urinary incontinence can have important social repercussions.

Causes of urinary incontinence are either established or transient (**Table 2**). Causes of established urinary incontinence include cerebral or spinal cord lesion, stroke, dementia, bladder disease, Parkinsonism and myelopathy. Latter are best recalled by student by using the mnemonic DIAPERS.

Table 2: Transient Causes of Urinary Incontinence

D	Delirium
I	Infection of urinary tract
A	Atrophic senile vaginitis
P	Pharmaceuticals or drug induced
P	Psychological causes like depression
E	Excessive urine output
R	Restricted mobility
S	Stool impaction

Evaluation of urinary incontinence is done by history and physical examination including neurological, rectal and gynaecological examination. Specific tests include cystoscopy, urodynamic studies, cystometry and sphincter electro-myography. Treatment depends on the cause. Many cases are relieved spontaneously. General measures include psychological support, behaviour modification, frequent toileting schedule, provision of bedpans and urinals, urethral sphincter and pelvic floor exercises, bladder training, treating of infections and in extreme cases supra-absorbable pads, pessaries and indwelling catheters. Biofeed training is sometimes resorted too. Pharmacological treatment includes anti-cholinergics and spasmolytics for hyper-reflexive or unstable bladders. Examples are oral imipramine 25 mg twice a day or oxybutyrin 2.5 to 5 mg three times a day or propanthaline. Oestrogens can be useful for atrophic vaginitis.

Menopause, Andropause and Hormone Replacement Therapy

As a short-term consequence of oestrogen deficiency, menopause is accompanied by vasomotor symptoms (hot flushes, sweating), urogenital atrophy (dryness of vagina, dyspareunia, urinary incontinence) and depressive moods while postmenopausal morbidity of coronary heart disease, osteoporosis, dementia and cancers is believed to be due to chronic oestrogen deficiency. Oestrogen or hormone replacement therapy (HRT) should therefore have some benefits. For premenopausal women, 20 µg of ethinyl estradiol plus 1 mg of norethindrone (progestin) daily for 21 days can eliminate vasomotor symptoms and restore regular cyclicity. They also protect against ovarian and endometrial carcinomas and increase the bone density. But, a history of thromboembolism, breast cancer, unexplained vaginal bleeding, smoking and liver disease is contradiction to the use of HRT. In that case, progestin only drugs, e.g. 0.35 mg of norethindrone daily or medroxyprogestrone (Depo-provera injection 150 mg IM every 3 months) can be given even though it does not regularise the cycles.

Although postmenopausal hormone therapy (PHT) is also known to provide benefits for vasomotor, urogenital and psychological symptoms, its long-term use in osteoporosis is no longer preferred due to serious side effects. With regard to colorectal cancer, some risk reduction has been reported with HRT, but its role is doubtful in cognitive decline and dementia. With regard to cardiovascular disease prevention also, role of HRT is of questionable value. In the heart and oestrogen/progesterone replacement study (HERS), not only the fact that 4 years of HRT resulted in no difference in coronary heart disease compared to placebo, but there was, in fact, a 50% increase in the risk of coronary events. Removing or adding of progestin made no difference to the results. Furthermore, results of Women's Health Initiative (WHI) study suggested an early increase in cardiovascular risk on HRT use both in terms of coronary heart disease and stroke.

Definite risks of HRT include endometrial cancer, venous thromboembolism, breast cancer and gall bladder disease. Risk of endometrial cancer goes up with the duration of therapy with unopposed oestrogen treatment. Use of progestogen eliminates this risk of endometrial cancer. Risk of breast cancer also increases with duration of oestrogen treatment and addition of progestin further raises this risk. Risk of thromboembolism is increased both by oestrogen alone and by oestrogen/progestin combination.

Like menopause in females, andropause occurs in males due to decline of androgenic hormone with ageing. Andropause, however, not universal to all men, is a gradual process and is not associated with any sudden event like menopause in females. There is a decrease in testosterone and serum inhibin with an increase in sex hormone binding globulin (SHBG). Apart from fatigue, depression, loss of energy and sex drive, andropausal males have increased risk of cardiovascular problems and osteoporosis. Treatment of andropause is testosterone replacement therapy. Testosterone enanthate can be given intramuscularly every two weeks. Testosterone should not be used for preventive purposes. Prostate and breast cancers, enlarged prostate, liver, kidney and heart disease and diabetes are contraindications for testosterone treatment.

Age-Related Macular Degeneration (AMD)

AMD is the leading cause of painless, slowly progressive visual loss in older persons. The term AMD is used to describe a variety of pigmentary and atrophic changes in the macula associated with the best corrected vision of 6/9 or worse. AMD is bilateral and progressive but its early recognition by routine eye checkups and photocoagulation form the most important strategy. Precise prevalence rates of AMD in our country are not available. In USA, AMD affects 11% of population of 65 to 74 years old and 28% of population over 74 years old. Because the ageing population is rapidly increasing, burden of AMD will increase in India also.

AMD is divided into two types: the dry or non-exudative form and the wet or exudative form, latter being less common, but encountered more frequently and is more responsible for

severe visual loss. Fluorescein angiography, amsler grid and contrast sensitivity are useful investigative methods to evaluate AMD. Treatment for dry AMD is non specific. Antioxidants and sunglasses have been used. Many patients benefit by organ LASER photocoagulation. Recurrences are, however, high after photocoagulation. Recently introduced non-LASERS as the form of photodynamic therapy (PDT) or transpapillary thermo therapy (TTT) are other therapeutic options. Monthly intravitreal injection of leucentis (ranibizumab) or avartin (bevacizumab) significantly retards visual deterioration and improves the vision in AMD cases.

Pressure Sores

These are also known as bed sores or decubitus ulcers. These lesions of skin breakdown occur with significant frequency in those older persons whose body parts are subject to pressure, friction, shearing (two layers of skin slide on each other) and maceration (softening of skin by moisture). Skin, subcutaneous tissue, muscle and even bone and joints can be involved. Risk factors include immobility, inactivity, faecal and urinary incontinence, malnutrition and decreased consciousness. Anaemia, infection, peripheral vascular disease, oedema, diabetes mellitus, stroke, dementia, alcoholism, fractures and malignancies compound the problem. In advanced cases, osteomyelitis may be present. Strategies to prevent bed sores include frequent changing in the patient's position, avoiding head end elevation beyond 30°, using special beds, surfaces like convoluted foam bed, alternating pressure mattresses, water mattresses, air fluidised beds and keeping the skin clean and dry. Treatment of pressure sores involves intensive nursing care. In the later stages, treatment of wound infection and mechanical, surgical or chemical debridement may be done. Irrigating solutions other than normal saline should be avoided. A wet-to-dry dressing is gently packed according to wound size and shape.

HEALTHY AGEING

Curative or tertiary care for numerous acute and chronic geriatric diseases is quite expensive and does not address the issue of maintaining long-term good health related quality of life by cost-effective strategies for disease prevention. Positive health practices of regular physical exercise, healthy diet, no-smoking, vaccinations, periodic checkups and stress management practised over the life course form the basis of healthy ageing and are capable of compressing the duration of period of morbidity in old age. Joint family system, informal support network, social and spiritual enrichment also contribute to healthy happy old age. Timely detection and correction of clinical and socioeconomic impairments and taking corrective measures compliments healthy ageing. Based on standard techniques, a comprehensive geriatric assessment of vision, hearing, locomotion, cognition, nutrition, depression, activities of daily living (ADL), instrumental activities of daily living (IADL), home environment, living arrangements, social and family support, financial dependence, smoking and alcoholism can be carried out by health provider in about 45 minutes.

REHABILITATION AND PHYSICAL THERAPY

Rehabilitation refers to a combination of physiatrist, i.e. physical, occupational and speech therapy, psychiatric counselling; social, and economic rehabilitation. Obviously, a number of experts are needed. In India, vital role of cost-effective community based rehabilitation (CBR) by trained community health worker and cost-effective indigenous assistive devices will be more relevant. Rehabilitation is often needed after prolonged bed rest, e.g. stroke, hip fracture, myocardial infarction, etc. to help regain functional independence and carry out ADL as a useful member of the society once again. Rehabilitation includes various exercises, training in ADLs (bathing, feeding, toileting and transferring) and IADLs (cooking, cleaning, shopping, etc.), treatment of pain and inflammation, etc.

TERMINAL AND RESPITE CARE

More than others, older persons need palliative or terminal care which is a total care of terminally ill patients with untreatable diseases like cancer and Alzheimer's and covers physical aspects like pain and distress as well as psychological, social and spiritual aspects. Terminal care can be offered at home, the hospice and at a general hospital. A hospice is neither a hospital, nor a home but in fact a combination of both where a dedicated team of physician, nurse, social worker and a counsellor provide effective relief through nursing, medical and social care, including bereavement counselling. General hospital settings are largely unsuitable for terminal care as the system is geared towards cure based on short-term stay while the home may be ideal. An important component of terminal care is care of the dying patient. Patient's preferences should dictate the type of care to be provided in bringing about a satisfying end from patient's point of view. A knowledge of law, will, power of attorney, and resuscitation is also important for patient's wishes.

Respite care is temporary supportive care of an older person by a substitute care giver. Respite care is often sought by the original care giver to, relieve the strain of care giving which may prove to be physically, emotionally and financially draining on him and other family members.

28.2 Sexual Medicine

Prakash Kothari

Sexual disorders are one of the most common disorders of human functioning and deserve attention of almost all physicians regardless of their particular speciality. An overview of sexual disorders is given in this chapter.

DIAGNOSIS OF A SEXUAL DISORDER

For a precise diagnosis of male and female sexual dysfunctions, four cardinal parameters need to be probed in particular along with the routine history of the patient.

Male	***Female***
Desire	Desire
Erection	Lubrication
Penetration	Penetration
Orgasm	Orgasm

These four parameters cover every possible facet of the reported sexual dysfunction and helps quickly in pinpointing the diagnosis. The evaluating method of history taking is precise and effective in a clinical/office set-up. This procedure has already been successfully tried in more than 50,000 patients.

Desire

Sexual desire is an instinctual inclination towards sensual gratification. In other words, it is the readiness to feel erotic. Increase or decrease in sexual desire can be evaluated by considering the information about frequency of sexual thoughts and masturbation or frequency of sexual intercourse. Increase or decrease in desire could be because of psychogenic or organic causes. The common psychological causes leading to decline in sexual desire could be because of depression, schizophrenia, following intake of certain drugs like anti-hypertensives, psychotropics, anti-androgens, cimetidine and certain ayurvedic preparations which contain rauwolfia alkaloids and addictive agents like *ganja*. Sometimes, dislike of partner or partner's behaviour, disturbed interpersonal relationship and fatigue may interfere with an individual's sexual desire. Testes manufacture testosterone and gets metabolised in the liver. Any testicular or hepatic pathology can lead to reduction in desire. Often chronic debilitating illnesses and androgen insensitivity syndrome could contribute to decline in desire.

Desire could increase in mania and in schizophrenia (because of loosening of inhibitions). Often sudden increase in desire could be following frontal lobe brain tumours, head injuries and temporal lobe epilepsy. It may also suddenly increase following intake of alcohol or marijuana.

Erection

It is essential to differentiate psychological erectile dysfunctions from organic erectile dysfunctions. If a man is able to achieve and/or sustain an erection of adequate quality in one situation (i.e. sleep, early morning on full bladder, during masturbation), but unable to achieve the same at the time of coitus; then the problem is situational (psychogenic) and not constitutional (organic). This is the hallmark to differentiate the two varieties of erectile dysfunctions. Psychological erectile dysfunction is characterised by sudden onset and selective nature while in organic erectile dysfunction, the onset is usually gradual and it is non-selective in nature. That means an individual will have erectile dysfunction in all situations and with all partners.

Erectile dysfunction could be primary or secondary. If an individual experiences the erectile dysfunction from the very beginning, it is known as primary and if it is developed later (after normal functioning for a specific period), it is called secondary.

Lubrication

Lubrication is the barometer for female sexual arousal. It is akin to erection in males. Decrease or increase in lubrication may lead to coital discomfort and/or pain. The common causes of inadequate lubrication are lack of adequate foreplay or arousal, local vaginal infections and endocrine imbalance. There could be increase in lubrication because of allergy or increased sexual arousal, often because of unknown aetiology.

Penetration

A man may have adequate sexual desire, stiff erection but would lose his stiffness prior to penetration. This is largely because of anxiety over sexual situation coupled with fear of failure. Sometimes despite the adequate erection and continued sustenance, penetration may not be possible because of inadequate knowledge of female sexual anatomy and sexual positions. Any evidence of pain in the penis at the time of penetration could lead to decline in erection. Often phimosis (pain and/or difficulty in retracting the foreskin over the glans penis) could be the cause. Vaginismus and rarely obstructive vaginal pathology in females could be responsible for a man's inability for successful penetration. Vaginismus is a condition where there is an involuntary spasm (severe contractions) of the outer one-third of the vagina during an attempt, or in anticipation of an attempt of vaginal penetration, thereby making penile penetration impossible. Hence, examination of the female partner is necessary prior to implementing the therapy even in a case of male sexual dysfunction. There are occasions where an individual may lose an erection immediately after penetration. This could be because of anxiety, distraction or a lax vagina leading to inadequate peno-vaginal contact.

Orgasm

Orgasmic disorders have so far been described as ejaculatory disorders in male despite the fact that there is a clear-cut neurophysiological distinction between the two. Orgasm occurs between the two ears whereas ejaculation in men and vaginal contractions in women occur between the two legs. Orgasm in

males is usually followed by ejaculation. However, orgasm can occur without ejaculation and vice-versa. In females, the peak of sexual pleasure, i.e. orgasm is usually accompanied by rhythmatic contractions in the vagina. The feeling of 'enough and nothing more!' is the litmus test to gauge whether a woman has experienced orgasm or not. Orgasm in a male and a female can be best defined as 'an explosive, cerebrally encoded, neuromuscular response, at the peak of sexual arousal by psychobiological stimuli, the pleasurable sensations of which are experienced in association with *dispensable* pelvic physiological concomitants'. Ejaculation in men and vaginal contractions in women is not a must for orgasm.

CLASSIFICATION OF ORGASMIC DISORDERS

Orgasmic disorders can be best classified as early, delayed, impaired (reduced) and absent (inability to experience) orgasmic responses.

Early Orgasmic Response (EOR)

If an individual experiences orgasm earlier than his expectation, which is within the rational limits, is termed as early orgasmic response. EOR is a better terminology than premature ejaculation in males as it does not propagate the myth that ejaculation and orgasm are synonymous and the diagnostic label focuses on exact pathology *per se (Though EOR in women is not described hitherto in the literature, it does exist in the females).*

Delayed Orgasmic Response (DOR)

Here, an individual does experience orgasm, but with a delay. The common causes include reduced arousal, fear, fatigue, anaemia, diabetes and reduced testosterone levels. Sometimes, inadequate penovaginal contact, e.g. lax vagina leading to not so firm grip on penis could be a contributing factor.

Impaired Orgasmic Response (IOR)

This categorises a condition in which there is reduction in the intensity of orgasmic pleasure. This could be psychogenic, due to low testosterone levels and sometimes following drugs like brown sugar and cocaine. Myopathies and neuropathies are known to cause this particular disorder.

Absent Orgasmic Response (AOR)

In this condition, an individual fails to experience orgasmic pleasure in the conscious stage. If there is no evidence of ejaculation including absence of sleep emissions, then this condition may be described as a 'total' AOR. Myopathies and neuropathies are the frequent causes of this particular disorder.

This classification is precise, focuses exactly on the pathology and does not propagate any myths. In addition, the classification has a distinct advantage of male and female parallelism. The classification EOR, DOR, IOR and AOR encompasses all the male and female orgasmic disorders.

Following the orgasm, the ejaculate usually comes out through the urethral meatus in spurts, i.e. antegrade ejaculation. But at times following orgasm, the ejaculate does not come out in antegrade fashion and instead goes backward into the bladder due to bladder neck disturbances, e.g. surgery involving bladder neck, etc. This is known as retrograde ejaculation. Sometimes, there may not be any formation of semen (absent ejaculate) for example in prepubertal boys, elderly individuals with very low serum testosterone and sometimes following long-term use of drugs like carbamazepine. In this situation, the orgasmic ability of an individual remains intact but there is no antegrade or retrograde ejaculation whatsoever. Sometimes, vaginal contractions in females are akin to ejaculatory contractions in males. Majority (but not all) of women may experience vaginal contractions at the time of orgasm.

EXAMINATION AND INVESTIGATIONS

Along with routine physical examination, one needs to check perianal sensations, anal sphincter tone and autonomic nervous system imbalance as and when required. Screening tests like routine blood (to rule out any anaemia), blood sugar fasting and 2 hours after lunch, lipid profile need to be carried out as a routine. Serum testosterone and sex hormone binding globuline (SHBG) may be advised if there is clinical suspicion of testosterone deficiency. Other hormone investigations like prolactin, thyroid may be advised to rule out any underlying pathology.

Other Investigations

Nocturnal penile tumescence rigidity (NPTR) monitoring

NPTR monitoring by Rigiscan can help in determining the rigidity and sustenance of erection. This is a precise and non-invasive test to rule out psychogenic erectile dysfunction or confirm organic erectile dysfunction.

Intrapenile injection

This procedure involves an injection of vasoactive drugs (papaverine combined with chlorpromazine or phentolamine and/or prostaglandin E1) directly into the corpora cavernosa of the penis. The erectile response and the amount of drug that is required to produce erection, gives a clue to the clinician whether the erectile dysfunction is psychogenic or organic.

Doppler examination

This is a non-invasive technique which helps in determining the patency of the superficial and deep blood vessels of the penis and their ability to dilate after an injection of vasoactive drugs.

Penile blood pressure

This is a screening test used for erectile dysfunctions. Penile systolic blood pressure (obtained by using a Doppler probe and tying a special cuff around the penis) divided by the systolic blood pressure of the arm, gives the peno-brachial index (PBI). Abnormal reading may give indication of vascular insufficiency leading to erectile dysfunction.

Infusion cavernosometry and cavernosography

Cavernosometry involves infusion studies with normal saline, helpful in diagnosing venous leaks responsible for inadequate erection. Cavernosography is a graphic study by X-rays of the penis (by injecting contrast medium), which determines the abnormal draining channels responsible for erectile dysfunctions.

Electromyography (EMG)

EMG studies could help to diagnose neurological lesions causing erectile dysfunction, impaired or absent orgasmic response and in conditions like squirtless seminal dribble (emission).

Note: EMG, infusion studies and PBI are not much utilised now.

TREATMENT

In psychosexual dysfunctions, the physician must emphasise the fact that he is treating a relationship and not the individual. The treatment aims at symptom removal which may require adequate blending of supportive psychotherapy coupled with behaviour modification and use of medication, etc. as and when necessary. Clearing of the myths and misconceptions and imparting adequate knowledge of sex and sexuality usually helps undo ignorance and reduce anxiety. However, if there is any evidence of major depression, schizophrenia, disturbed marital relationship and those with rigid defenses need to get their problem sorted out prior to implementing sex therapy.

The starting point for the most sexual dysfunctions would be sensate focus exercises. This includes sensuous interplay by avoiding sexual interaction. Intercourse is forbidden in initial stages, hence the performance anxiety is allayed completely. The couple is immersed in situation of physical intimacy short of intercourse. The initial sessions consist of tactile stimulation without any genital touch. Here, one partner tries to explore the areas with maximum arousal and verbalises his/her feelings, likes and dislikes. Partners are requested to touch each other in a way that helps trigger relaxation and not anxiety. If one is passive during an exercise, and the partner's touch is triggering the anxiety, then one needs to convey the same to the partner. The main thought patterns which contribute to anxiety are spectatoring, racing thoughts and performance thoughts. These exercises help to relieve sexual boredom and gradually increase sexual arousal. Although sexual desire and arousal are not the same, often they do reinforce each other. Enhanced arousal leads to increased sexual desire which in turn leads to more arousal. The main focus is on non-demand interactions. When you are the active partner, caress for your own pleasure. When you are passive, allow yourself to follow the sensations and enjoy them without any anxiety to respond. Initially, the genital touch is prohibited but later genital touching is permitted without demand to produce erection.

Treatment of Male Sexual Disorders

Strategy for psychological erection disorders

- Pleasure without erection
- Pleasure with erection
- Extra vaginal orgasm
- Penetration without orgasm
- Coitus

Some cases of psychological and organic erectile dysfunctions can be helped effectively by medicines like sildenafil citrate (50 to 100 mg). The medicines need to be taken an hour before the anticipated sex act, preferred on empty stomach and one can take maximum of one tablet in 24 hours. The effect usually lasts for 6 to 8 hours. This particular tablet has no role on desire or orgasm, but it helps to enhance the rigidity and sustenance of already achieved partial (semi stiff) erection. This medication is contraindicated in those who are taking nitrates (for heart conditions or hypertension), alpha blocker for prostate problems and those who have retinopathy. The other drug is tadalafil (10 to 20 mg) that has a more lasting effect up to 24 to 36 hours. However, patients reported a shade better quality of erection with sildenafil as compared to tadalafil (**Table 1**).

Table 1: Medicines and Its Side Effects

Generic Name	Sildenafil	Tadalafil*
Availability in milligrams	25/50/100	10/20
Onset of action (minutes)	30 to 45	30 to 45
Duration of action in hours	6 to 8	24 to 36
Interference in absorption with food	Yes	No
Side Effects**		
Headache	+++	++
Visual disturbances	++	
Flushing	++	++
Back pain and myalgia	+	++
Dyspepsia	+++	++
Rhinitis	++	++
Flu-like syndrome	+	++

** May cause dizziness; ** As encountered by the author in his clinical practice*

In those patients, where there is evidence of testosterone deficiency (revealed by clinical and metabolic evaluation), testosterone may be implemented orally or by injection. Intramuscular depot injections of testosterone undecanoate need to be taken once in 3 months. Often these medicines are more effective, once the testosterone deficiency is overcome. In elderly individuals, however, care needs to be taken to do prostate specific antigen investigation and transrectal ultrasonography of prostate prior to implementing testosterone therapy.

The second option could be intra-penile self injection with vasoactive drugs, such as papaverine in combination with chlorpromazine, phentolamine and prostaglandin E1. Prostaglandin E1 can be used alone also. However, 1 out of 3 patients report of pain in the penis following injection of prostaglandin E1. Sometimes the erection achieved by the papaverine injection fails to subside leading to priapism. In such situations, physicians should be aware of the method to relieve the same, failing which a surgeon can help drain the blood from the penis resulting in detumescence of the penis. However, prostaglandin E1 is relatively free from the side effect of priapism, though more expensive and has difficult availability.

If the above procedure fails, one may consider penile implant prosthesis surgery for the erectile dysfunction. Following this surgery, the pleasure at the time of orgasm and the ability to father a child remains unchanged. The types of penile implant surgeries available are listed in the **Table 2**.

Table 2: Types of Penile Implant Surgeries

	Non-Inflatable	Inflatable
Cost	Less	More
Appearance	Always erect	Under your control
Comfort	Less	More
Hardness	Fixed	Adjustable
Device failure	Less	More
Surgery	Less time	More time and skill
Failure rate	Less	More
Types	Flexible	Three-piece
	Malleable	Two-piece
		One-piece

Treatment of Orgasmic Disorders (Male)

Early orgasm (Premature ejaculation)

Many techniques have been used to delay orgasm. The methods commonly used may include doing mental arithmetic during the sex act, applying a local anaesthetic ointment to the glans penis prior to penetration and wearing a condom to decrease sensitivity. Other methods include the following:

- Pelvic muscles exercises
- Interrupting and restarting the flow of urine repeatedly
- Practising *Vajroli mudra* and *Ashwini mudra*
- The 'squeeze or stop-start' technique

The author in his clinical practice found these methods good as adjuncts, but not as a mainstream treatment regime.

Paroxetine (20 mg), or clomipramine (25 mg), to be taken 4 hours and 6 hours, respectively prior to the anticipated sex act help delay climax in most individuals. Sometimes, a combination of paroxetine (10 mg) and clomipramine (10 mg), 6 hours prior to the anticipated sex act has also proved beneficial. Depoxetine (30 to 60 mg), 2 hours prior to coitus can help delay in climaxing in most individuals. This medicine has relatively fewer side effects and found to be more effective.

Delayed orgasm (Retarded ejaculation)

Along with supportive psychotherapy and behaviour modification, enhancing sexual arousal is the main key of the treatment programme. Researchers have observed that diabetes may be the cause of orgasmic/ejaculatory disturbance. However, it seems to impair erectile mechanism much more frequently as compared to orgasmic mechanism. Testosterone deficiency, if present, needs to be treated and may help increase sexual arousal in cases of delayed orgasmic responses. Pubo-coccygeal (PC) muscle exercises may prove to be beneficial. Positions like woman's legs crossed and doggie usually prove beneficial in providing better grip and friction, leading to enhanced sexual arousal culminating in early climax.

Impaired and absent orgasm

Addictive drugs like brown sugar and cocaine are known to cause these dysfunctions. Hence, it is best to remain away from them. PC muscle exercises may prove to be beneficial. Enhanced sexual arousal by any means may prove useful. Vibrating the undersurface of the glans penis by a simple body vibrator can help achieve orgasm/ejaculation.

Treatment of Female Sexual Disorders

Vaginismus

Treatment essentially comprises of supportive psychotherapy, behavioural desensitisation, relaxation exercises and gradual insertion of user friendly vaginal dilators/trainers. Anxiety born out of any myths and misconceptions needs to be cleared. It needs to be emphasised that vagina is highly elastic and is capable of accommodating any size of object, be it a finger for genital examination or head of a baby during delivery. Prognosis in the treatment of vaginismus is excellent. No psychotropic drugs or surgery is required in the course of treatment.

Painful sexual intercourse (Dyspareunia)

Most often, when the woman is not adequately aroused and the man makes an attempt to enter, because of lack of lubrication, it leads to painful penetration at the time of intercourse. Hence, devoting more time to foreplay helps resolve the majority of problems. Local vaginal infection and hormone imbalance could also hamper lubrication. Other less common reasons for persistent pain at the time of intercourse could be because of hymenal and other obstructive vaginal pathology, urethral disorders or congenital malformations of the vulva or vagina. It could also occur following post-operative scars and atrophic vulvo-vaginitis, common in menopausal years.

Orgasmic disorders

Early orgasm in females has not been described hitherto. But this particular disorder needs to be treated in the same manner as one is treating the early orgasmic disorder (premature ejaculation) in males. Delayed/impaired/absent orgasm in females can be best helped by increasing sexual arousal, pelvic floor muscle exercises, modifying the coital position, using a lubricant or substituting necessary diet and/or hormones (if there is a clinical and metabolic evidence of deficiency). Supportive psychotherapy and behaviour modification are of crucial importance.

Lax vagina

This may occur following childbirth. It can be best prevented by proper management of labour with perineal support, an adequate and timely episiotomy and perinatal exercises. A lax vagina can be benefitted by Kegel's exercises. It involves contraction of the perineal muscles—a phenomenon akin to holding the urine and releasing it. Twenty such contractions and relaxations, three times a day, may help increase the muscle tone. If this does not work, one may consider vaginal reconstructive surgery for severe cases.

While treating the sexual disorders, the physician needs to be comfortable with his own sexuality as well as the subject of sexuality. Human understanding, empathy and offering of the adequate sex knowledge are the most powerful remedies, the value of which tends to be neglected in this modern age. Their increased application can obviate the majority of the use of tranquilisers and the so called sex tonics.

28.3 Sports Medicine

Anant Joshi

Since the beginning of the modern Olympic age, the world of sports and athletic performance has undergone several important transformations. Sports have become professional; it pays to play which makes it mandatory to give your best and for that, fitness is the key.

An offshoot of the corporate culture, recreational athletics (weekend warriors) are on the increase. The overburdened executive, who exercises over weekends to get rid of stress, is often more concerned about his weight, aerobic capacity, strength and this is injury prone than the professional athlete.

Exercise science or the science of exercise is the application of medical sciences to sports to better human performance and the application of sports or exercise as a therapy in the management of disease.

Sports medicine, in the present day sense, has a relatively short history. In 1912, the first official Congress for Sports Medicine was held in Germany. The modern definition of sports medicine was coined in 1958 in Cologne-'Sports Medicine includes those theoretical and practical branches of medicine which investigate the influence of exercise, training and sport on health and disease and study the bad effects of lack of exercise to produce useful results for prevention, therapy, and rehabilitation of the athletes.

SPORTS MEDICINE AS A SPECIALITY

With sports becoming increasingly professional, the athlete needs all possible inputs to improve performance. A top tennis star today moves with his contingent of a personal trainer, a coach, a psychologist and a nutritionist.

Till recently, sports medicine was a hobby of doctors who participated in sports. Today it is a profession and sub-speciality in itself. Departments of exercise science exist in universities offering degree and diploma courses. Olympic federations and national sports team have their own sports testing facilities. Exercise physiologists, physicians, surgeons, psycho- and physio-therapists, trainers are all part of an ever expanding team of sports medical specialists.

ATTRIBUTES (COMPONENTS) OF FITNESS

For the athlete, 'your weight is right for your height' is just not enough.

Sports activities can be divided according to their energy requirements, motor skills requirement and power requirements. Some activities are predominantly aerobic, e.g. long distance running; others are anaerobic, e.g. sprint events; and still others require a combination of both, e.g. middle distance running. Football, rugby, badminton are examples of activities that require alternate aerobic and anaerobic commitment. Power events often demand great acceleration like linear as in shotput and javelin throw, and circular or centrifugal as in discus and hammer throw. Gymnastics and diving are events that require extreme skill, although not by the exclusion of strength or power.

Every sport requires a blend of different fitness attributes. These include aerobic, anaerobic capacities, muscular strength, local muscular aerobic and anaerobic endurance, muscular power, flexibility, speed of reaction and motor correctness.

FUNCTIONAL EVALUATION OF AN ATHLETE

Unlike the usual medical consultation, an athlete needs an evaluation of his strength, flexibility, endurance, power and reaction time. These are parameters that are paramount for better performance rather than staying alive.

The functional evaluation of an athlete is a complex task. It is not just sufficient to know about the functioning of the heart, lungs, nervous system and the peripheral circulatory system, but the functioning of the organism during muscular work of high intensity is also necessary. In addition, the movement and mechanical aspects required of the human machine during specific sports should also be studied. This calls for close co-operation between a physiologist and a biomechanics expert. Some of the parameters investigated during fitness testing of an athlete include cardiac frequency (at rest, during work and during recovery), oxygen consumption in relation to weight, oxygen pulse (VO_2/cardiac frequency), pulmonary ventilation, respiratory quotient and lactic acid estimation. Muscular strength, flexibility, power, endurance, reaction time give an estimate of musculoskeletal and neuromuscular conditioning.

Athletes are tested in a lab setting or 'on the field' environment. Testing a swimmer on a treadmill makes little sense and hence a variety of ergometers have been designed to simulate sports specific actions, the swimming fluke being an example.

'THE ATHLETE'S HEART'

Chronic physiological overload causes an increase in the heart size, as well as increase in the heart's range to perform and is as a result of physiological hypertrophy of the muscle mass (Linzbach) and of regulatory dilatation of both ventricles. This is in opposition to an increased heart size due to disease (myogenic dilatation) resulting from overload (pressure or volume) or primary myocardial damage. During the years of growth, between 14 and 18 years, endurance training results in a particularly rapid increase in heart size. Physicians unaware of the athlete's heart are often responsible for declaring an athlete with a large heart as 'unfit'.

SPORTS THERAPY

Remedial exercises have been used in treating ailments as diverse as osteoarthritis and osteoporosis, to hypertension and coronary artery disease, and to counteract the effects of ageing. Osteoarthritis needs non-load bearing exercises and

osteoporosis just the reverse. Aerobic exercise is used as a 'fat burner' in the management of obesity. 'Endorphins' liberated during exercises act as 'stress busters'.

Obesity not caused by dysfunction of the endocrine system, the main cause seems to be decreased energy output together with excessive energy input. Even with a well-controlled diet it is difficult to lose weight. In order to come up with an exercise programme for an obese individual, it is important to evaluate how healthy the subject is and his or her residual physical capacity. This clinical and instrumental check-up should help the physician assess the cardiovascular, respiratory and musculoskeletal systems and gauge the percentage of body fat that needs to be reduced. It is also important at this stage to know the factors that would limit or hinder the training programme, e.g. presence of arthritis or asthma. A specific and personalised training routine can then be planned. The motivation and general psychological state of the obese patient must be considered to reduce the frequent phenomenon of 'quitting', which is often the basis of failures. Physical reconditioning of the obese must be programmed to improve body fat mass to lean tissue mass, reactivate muscles that have become hypotonic and hypotrophic due to disuse, restore physiological mobility of major joints and recondition cardiovascular and respiratory systems.

The training programme can be divided into three major parts:

First, rhythmic, low frequency and intensity callisthenic type exercises that will improve mobility. Once mobility is achieved, muscular conditioning through anti-gravitational stimulus like lifting light dumbbells or medicine balls.

The second part is aimed at improving the efficiency of the cardiovascular, respiratory and musculoskeletal systems. Exercises are now based on 'movement' and have to be of 'sub-maximal' intensity where heart rate rises to 60% of theoretical maximum heart rate. Workloads should be progressively increased. For the obese, initially, instead of running or walking, cycling or swimming is recommended for weight loss.

'Endurance' sports activities can now be introduced for a sustained weight loss or maintenance programme.

Thirdly, 'balanced training' or 'controlled' exercise is fundamental to fitness and should be designed on a scientific basis. The importance of 'rest' cannot be over emphasised.

Prescribing exercise is an art by itself. The type, intensity, duration and frequency of exercise are quantified. Periodic checks help in monitoring the progress or usefulness of exercise and help in subsequent modifications. Sports therapy is not used in isolation. It supplements other methods of treatment. Exercise can reduce drug dependence and dosage in the management of ailments like diabetes and hypertension.

THE SCIENCE OF TRAINING

Training, a systematic repetition of exercises, aims at achieving a better performance. Science has become increasingly important in the process of training and enables training to be more focused.

General and specific elements of training have to be analysed separately. As an example, let us consider strength as one of the motor characteristics that needs to be developed. Various methods of training contribute to different kinds of muscle strength. Isotonic or dynamic exercise result in lesser increase of strength but its effect lasts longer than the isometric type and it causes less co-ordination disturbances.

Principles of Exercise

Specificity

'You get what you train for', adaptation is specific to a stressor and the affect of a stressor is specific to an individual. The specific adaptation to imposed demand (SAID) principle is the cornerstone of athletic training. Thus, strength training will bring about greater changes in muscular strength than in cardio-respiratory fitness.

Overload

Christensen in 1931 showed that training with a standard workload substantially lowered the heart rate; say 180 to 160 beats per minute. Further training of the same intensity did not modify this heart rate response, but if training was increased in severity, the original work could be completed with a slower heart rate, perhaps down to 140 beats per minute. Progressive increase could be in terms of extent (more km, repetitions) or intensity (more kg, faster runs) or in terms of density (shorter intervals of rest between exercises, repetitions, sets, units 2 to 3 per day) and so on.

Reversibility

'Effects of exercise are not permanent'. Just as regular exercise produces training, subsequent lack of exercise produces 'de-training'. When either intensity, duration, frequency of exercise is reduced, the degree of adaptation brought about by the training load will gradually weaken. Strength losses are faster than mobility losses. Status improvements brought about by 'special' methods over a short term are lost quicker than those brought about by 'slower' methods over a longer term. If a limb is totally immobilised, the losses may be up to 5% per day.

Cross transfer

Some cross transfer effects of exercise do occur. Overloading one area will also put some extra stress on others as well. Although endurance running is not the ideal method for developing leg strength, a runner will have greater leg strength than someone who does not exercise at all.

Repeated overstressing causes progressive fatigue

Physical training is only one of the stressors that bombard the body everyday. Domestic and social life, career studies, institutional demands are all stressors and eventually add up to contributing to a fatigue state.

Science has lent objectivity to training. Recent studies have made it possible to measure the limits of physical adaptability to sports training – maximum muscle power can be increased by 50%; aerobic power by 35% and anaerobic power by 60%.

NUTRITIONAL ASPECTS: FOOD AND FLUID

Dietary manipulations to increase carbohydrate loading are carried out by endurance athletes for increasing muscle glycogen stores two- or three-fold.

While lack of certain foodstuffs may bring about a decrease in functional capacity, or even illness, it has yet to be proved that excessive consumption of foodstuffs will increase functional

capacity. Most people over-estimate their dietary requirements. Overeating causes decreased performance and faster ageing than a well balanced diet.

Seventy per cent of the human body is composed of water, most of which is contained inside cells. Heat and stress cause sweating. When sweating, fluid is drawn from this intracellular supply with resulting adverse effects on cell metabolism. Fluid loss becomes apparent when 1% to 2% of the body weight has been lost as sweat. When fluid loss amounts to 4% to 5% of the body weight the capacity for physical hard work is reduced by nearly 50%. During exercise in a hot environment, water loss can be considerable and can amount to 5 litre or more per hour.

To maintain physical efficiency, fluid replenishment is necessary. Cooler fluids (25 to 30°C) are absorbed better than hot ones. Presence of glucose and other sugars retards this absorption. Up to 60% to 70% of a 400 mL draft of water leaves the stomach in 15 minutes while only 5% of a drink containing 10% sucrose leaves in the same time. For rapid absorptions, drinks should not contain more than 2.5% of carbohydrates.

It is well known that sweat contains electrolytes in addition to water. However, the concentration of sodium and chloride in sweat is only about one-third that of plasma, so that relatively more water is lost than salt and sweating leaves body fluids more concentrated. Costill has suggested that electrolytes be replaced after exercise by drinking a glass of orange or tomato juice and by adding a little more salt to diet.

Taking into account fluid absorption and stomach emptying times, it has been recommended that fluid replacement should be done by the athlete during less intense periods of exercise and less concentrated solutions should be drunk at more frequent intervals. The sensation of thirst is not an accurate guide when it comes to replacing fluid loss by sweat. Slaking one's thirst generally provides only half the amount of fluid required. Anyone who indulges in strenuous physical activity is advised to drink considerably more than he thinks he needs.

SPORTS INJURIES

The only time the human body is called upon to surpass itself deliberately is during sports. An athlete gives 'his heart out', exercisers 'go all out', and in trying to overcome the physical, physiological and psychological limits, injuries do occur.

A wide spectrum of sports injuries are seen from niggling sprains and career-threatening ligamentous tears to life-threatening dislocations.

Injury frequency has increased drastically with the development of professional and recreational sports activities. Speculations have been made about possible factors that may influence the occurrence of such injuries. Today's athletes have increased the intensity and duration of training and that too in unfavourable environmental conditions. Exercising in groups where the fit and the unfit are clubbed together, like in an aerobics class, results in the uninitiated individual doing more than what the body can take.

Sports injuries may be acute or chronic, 'extrinsic' or 'intrinsic'. Extrinsic injuries are those caused by faulty surfaces, shoes, protective gear, sports apparatus or apparel and environmental factors. Intrinsic injuries which account for a majority of sports injuries are a result of faults in body conditioning (through training) or technical errors (poor sports technique).

Orthopaedic surgeons who are trained to tackle bones and joints are often inadequately exposed to soft tissue musculoskeletal injuries. Muscle injuries which by far account for most sports injuries are thus often underdiagnosed, missed and mistreated. Shin splints and tennis elbows are poorly understood and treated. A tennis elbow may be caused by faulty technique—using the wrist, elbow in front of the body or wrong grip size or just heavy balls. Treating all tennis elbows by pain relieving medication or a steroid injection without analysing the cause would be foolhardy.

OVERUSE INJURIES

A category of injury peculiar to the athlete is an overuse injury. Athletes often overuse and abuse their bodies due to the misconception amongst athletes and coaches that more is better.

Overuse injuries do not immediately cripple the athlete. Repetitive exposure of tissue to low magnitude forces results in injury at the microscopic level. Repeated overload as in running or jumping are often associated with overload injuries to the lower extremity. In the running gait, a force in the range of 3 to 5 times the body weight ascends up the lower extremity at heel strike. This force behaves like a sound wave with a short duration (20 to 40 ms) with rapid dissipation. Considering an impact of 250% of the body-weight, a runner absorbs at ground contact 110 tons on each foot per mile. The forces for longer distances can be imagined, considering that a long distance runner who runs 100 miles per week plants each foot about 3 million times a year. Factors predisposing to overuse injuries can be intrinsic or extrinsic. Intrinsic causes would include malalignment (pronated feet, femoral anteversion), leg length discrepancy, muscular imbalances. Poor training methods (exercising to the point of pain), hill work, sloping or hard surfaces are extrinsic factors that can predispose to injury. Although the muscle tendon unit is the most commonly affected structure, even bone is not immune to overuse injury.

Treatment

Overuse injuries are treated by rest, relief of local inflammation, and the gradual reintroduction of controlled and protected activity. If the recurrence is to be prevented, it is also important to ensure that the future training load is controlled more carefully and adjusted more gradually. For example, changes from endurance running to sprinting, or from road to track, must be gradual. Shoes should be examined for the adequacy or arch support and heel-cushioning. The squash racket's handle should be thickened to prevent further strains of the common extensor origin. The swimmer's arm action should be analysed to reduce impingement of rotator cuff tendons on the coracoacromial arch. The road runner should be advised to interpose the occasional run on grass.

DIRECT SOFT TISSUE TRAUMA

Many sports put the participants at risk of direct trauma to muscle, tendon, ligament, and subcutaneous tissues by contact with the ground, the opponent, a ball or an opponent's bat. Strict enforcement of the rules, a properly prepared playing surface, and tuition in the skills of the sport will prevent some of these injuries but they can never be avoided completely.

Acute Treatment

Much of the pain and disability resulting from soft-tissue trauma is not due to the injury itself but to bleeding in and around the damaged tissues. Extravasated blood causes pain and limitation of movement at first by a space-occupying effect, then by causing local inflammation. Later, rehabilitation is hindered by fibrotic adhesions. Acute management concentrates on preventing this sequence of events.

The prevention of bleeding depends on ice compression, and elevation (mnemonic 'ICE'). The local application of cold for 10 to 20 minutes will induce vasoconstriction and has the added benefit of relieving pain. Venous hydrostatic pressure at the site of injury is reduced by elevation of the injured limb for 2 to 24 hours. Extravasation of blood is limited by a compression bandage applied immediately after the ice is removed, and maintained for 2 to 24 hours. Elevation is not only the simplest of the three measures to implement, it is probably also the most important and the most neglected.

Recovery is faster if a nonsteroidal anti-inflammatory agent is administered, in full dosage, for 3 to 5 days after soft-tissue injury. Prompt orthopaedic advice should be obtained.

Rehabilitation

Absolute rest is usually inappropriate after the first 24 hours. Selective, graded and protected activity is preferred to immobilisation. Before return to competition can be permitted, balance and co-ordination skills must be relearned.

STRESS FRACTURES

The repeated application of stress to a bone may result in a 'fatigue' or 'stress', fracture. The most common sites are the tibia, the distal fibula, and second and third metatarsals. Femoral stress fractures are also seen. There is no history of acute trauma; there need not be any pain at rest. Initial radiographs may appear normal, and later may show callus formation. Radioisotope bone scan may be necessary to confirm the diagnosis. A simple bedside test is the sharp pain produced by insinuation of the suspect of the area of bone with a physiotherapist's ultrasound applicator.

Treatment

Aims of treatment are to avoid complete fracture and allow the bone to heal. This requires temporary abstinence from the sport. Weight bearing should be avoided if it is painful. Strength and endurance should be maintained by isometric exercises and by a change of activity like cycling or swimming (for metatarsal or fibular fracture).

FRICTION SYNDROME

Local inflammatory response to overuse may be evident with pain, swelling, discolouration, warmth, and palpable crepitations. Examination may reveal nothing. Re-examination immediately after a provocation test may be helpful.

Treatment

Nonsteroidal anti-inflammatory drugs, 1 to 2 weeks of relative rest, stretching, isometric exercises and gradual resumption of activity, are advocated. Local injection of steroids may be helpful, if the above measures fail. Surgical decompression is occasionally required.

SUDDEN CARDIAC DEATH

Sudden cardiac death during sports tends to attract the attention of the press but is in fact very rare. Although vigorous physical activity carries a transiently increased risk of sudden cardiac death, this is greatest in those who are habitually least active and are overweight than in those who are most active.

Prevention

Exercise electrocardiography has been advocated as a screening procedure for all middle age sportsmen. However, it is not a prerequisite for exercise training unless there are symptoms suggestive of myocardial ischaemia, strongly positive risk factors for coronary disease, a family history of premature sudden death or dysrhythmias, or a personal history of exercised-induced syncope. Instead, anyone unaccustomed to vigorous exercise should be taught that its intensity should be at first modest and should increase gradually. The exercising person should also be taught to recognise symptoms of underlying cardiac disease and seek medical advice.

TRAUMA AND VIRAL INFECTIONS

Herpes simplex virus infection may occur due to abrasive contact during sport, especially between wrestlers or between rugby front-row forwards. Hepatitis B and HIV infection may occur as a result of contact of one player's blood with another player's broken skin. This may be seen in wrestling, rugby, judo and boxing.

OTHER EXERCISE-INDUCED ABNORMALITIES

These are amenorrhoea, iron deficiency anaemia and rhabdomyolysis.

28.4 Diet in Medical Diseases

Siddharth N Shah

Significant advances in the area of clinical nutrition have occurred in the last decade. Healthcare professionals and the patients have appreciated the role of nutrition in promoting optimal health. This nutrition awareness has created the need for more and precise information on all aspects of nutrition and clinical dietetics related to patient care. This chapter primarily conveys information concerning the role of diet in few diseases and also gives diet plans for the same. The general principles of diet therapy are listed in **Table 1**. However, it is recommended that each patient must be assessed individually and a diet plan formulated considering his/her nutritional status, associated illnesses and various deficiencies that need to be corrected.

Table 1: Guidelines to Good Dietetic Therapy

Reach and maintain ideal body weight
Be careful of serving sizes
Avoid skipping meals
Increase your daily activity
Preserve lean body mass

DEVELOPING A NUTRITION PLAN

Diet is the cornerstone in management of various diseases. To lose weight, for heart diseases or for diabetes, a few small changes in eating habits can make a big difference. Healthy eating does not have to be monotonous. The easiest approach to improve eating habits is to use the food pyramid as a guide (**Figure 1**).

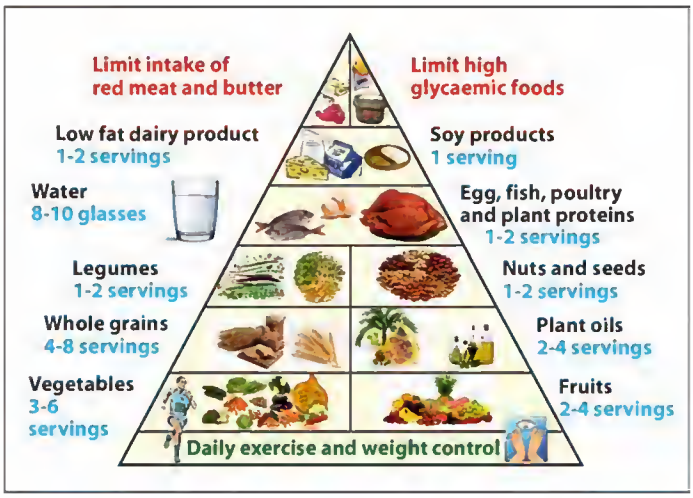

Figure 1: The food pyramid. Each section of the pyramid is a food group. The smaller the section, the less of that type of food one should eat.

OBESITY

Obesity is a predisposing factor for various complications like atherosclerosis, diabetes mellitus, arthritis and high blood pressure. A diet low in calories and fat, and high in fibre is recommended. It is designed to provide less than the required energy by the body and use up the fat stores of the body, especially with a structured exercise programme, which is a balance of energy intake versus energy expenditure.

Dietary Guidelines for Obese Patients

- Set realistic short-term and long-term goals.
- Avoid fasting or feasting/skipping any meals.
- Always eat breakfast with good choice of cereals.
- Do not eat in between the meals. Have low calorie/high volume food items.
- Avoid ready to eat food items, concentrated food items like sweets, fried items, etc.
- Do not sleep immediately after eating.
- Do not eat while watching television, opening refrigerator, cooking, serving or reading.
- Thoroughly chew each and every morsel of food, remembering that it takes around 20 mins to realise satiety.
- Avoid alcohol and follow dietary recommendations.
- Physical exercise is a must to burn away, excessive fat.

Principles of Diet

Energy

A low calorie balanced diet providing atleast 1,200 Kcal/day is considered safest and most effective for weight loss in majority of obese patients. Energy restriction below 800 to 1,000 Kcal/day is not recommended as it may lead to deficiencies of other nutrients and also the body goes in a negative feedback of conserving energy (reducing BMR). A triad of a calorie restricted balanced diet, increased physical activity and control of associated illness and various deficiencies goes a long way to achieve and maintain weight loss. Unrealistic/very low calorie/starvation diets may lead to yo-yo syndromes, gallstones, etc.

Protein

A normal intake of 1 g/kg ideal body weight (IBW) is recommended for tissue repair.

Fats

Fats in the diet should be restricted as they are concentrated sources of energy. Both visible and invisible fats should be restricted in the diet. A minimum level of 15 to 20 g visible fat should be maintained in the diet, to provide palatability and essential fatty acid requirement.

Carbohydrates

Simple carbohydrates should be avoided. Potatoes, sweet potatoes, yam, banana, rice should be used prudently. A diet high in fibre provides satiety and long-term compliance.

Vitamins and minerals

Multivitamin and mineral supplements may be advised because calorie-restricted diets may be inadequate in some nutrients. Extra salt in the diet causes retention of water in the body. Thus moderate salt restriction is helpful.

Water

Water is allowed in liberal quantity. Fluids like thin buttermilk, dal water, unstrained soups, sugar free lime-water provide variety in the fluid and also fill-up the stomach; thereby reducing subsequent meal intake.

Fibre

High fibre foods like green leafy vegetables and fruits can be included in the diet freely in the form of thoroughly washed vegetable salads (raw or boiled), unstrained-unseasoned soups. These foods give a sense of satiety and regulate bowel movements too.

Food exchanges

A food exchange is a grouping of food items which are of approximately similar nutritive value; so as to enable one to plan and select meals with ease and convenience and also provide variety.

Cereals

Each of these provides 100 Kcal.

Two medium size dry chapatti = 1 cup roasted/plain rice flakes = 1 cup cooked rice = 1 cup rawa upma = 1 bread slice (large).

One can have around 7 to 10 exchanges or servings daily, depending upon the requirement.

Pulses and legumes

Each of these provides 100 Kcal.

Two cups thin dal = 1 cup thick dal = ¾ cup cooked pulses = 1 big cup sambhar.

One can have 2 to 3 exchanges each day.

Nuts and oilseeds

Each of these provides 100 Kcal. Three-fourth cup grated fresh coconut = 1 handful of groundnuts/cashew nuts/sesame seeds/almonds.

Vegetables

Each of these provides 25 to 30 Kcal

Veg. A: 1 big cup of dark green leafy vegetables.

Veg. B: three-fourth cup of any other vegetables like brinjal, beans, ladies finger.

Veg. C: half cup root vegetables like potato, beet root, yam, sweet potato, etc.

One can have 2 to 3 servings each day, depending on whether one is on a calorie diet and/or carbohydrate enriched/restricted diet plan.

Fruits

One fresh medium sized citrus fruit/half pulpy fruit supplies roughly 50 Kcals.

One can have 2 to 3 exchanges each day. Fruits are best eaten as a mid-morning or a mid-evening snack rather than along with the meals.

Milk and milk products

Each of these gives 100 Kcal.

One-cup cow's milk/3/4th cup buffalos milk/1-cup curds/8 medium sized pieces of paneer, made from cow's milk.

One can have 2 or more exchanges each day.

Fat

Each of these gives 90 Kcal.

Two tsp of oil/ghee/vanaspati/3 tsp of butter.

One can have 2 to 3 exchanges each day.

Sugar

Each of these gives 100 Kcal.

Five tsp of sugar/jaggery/2 tsp of honey.

One can have 1 to 2 exchanges each day.

Meat

Each of these provides 85 Kcal.

One serving of meat/fish/poultry = ½ cup cooked curry/1 egg (boiled).

Vegetarians may substitute meat exchange with an extra exchange of pulse or milk.

One can have 1 exchange each day.

Free foods

Black-coffee/tea, plain sodas, unsweetened lime juice, clear soups, thin buttermilk made from double skimmed milk curds, masala (without coconut or oil base), ginger, vinegar, gelatine (unsweetened), coriander, mint, garlic, mustard, bay leaf, cinnamon, nutmeg, pepper.

A prudent diet, structured exercise programme (to preserve the lean body mass), a positive attitude, a determination to improve quality of life (QOL) remains the cornerstone of any diet programme. Weight loss programme can majorly (with the exception of genetic/physiologic causes) be termed as 'lifestyle modification programme'.

DIABETES MELLITUS

Diabetic diets need not a complete deviation from the normal diet. A traditional Indian diet can be made suitable for diabetics with few modifications in the nutrient intake based on age, sex, weight and physical activity. The diet is designed to improve blood glucose and lipid levels, encourage healthy eating patterns, promote consistent food intake and avoid undue starvation or overeating, thereby improving quality of life. In many ways, it is similar to a weight loss diet.

Principles of Diet

Energy

The calculated calorie requirement should allow the patient to achieve and maintain ideal body weight (IBW) and the desired waist-hip ratio (WHR). The total calorie requirement is calculated based on the level of physical activity and an individual's actual weight. Based on body weight, the following guidelines can be used for calculating the energy requirement of diabetic patients.

For overweight person – 20 Kcal/kg/day IBW

For ideal weight person – 25 to 30 Kcal/kg IBW

For underweight person – 40 Kcal/kg/day IBW

For pregnant diabetic woman – 30 to 35 Kcal/kg/day IBW

The total daily intake of calories from the various macronutrients can be distributed as shown.

Distribution of calories

Carbohydrates should constitute 60% to 65% of total calories, proteins and fats 15% to 20% each.

These can further be divided into meals, which can be small frequent meals, avoiding the load on pancreas and stimulating it to produce insulin in regular doses and intervals, or it can be modified to the lifestyle of the patient.

Carbohydrates

An Indian diet predominates in this nutrient. Diabetics need not restrict carbohydrates. Simply modifying the type of carbohydrates in the diet will help achieve euglycaemia. Simple carbohydrates obtained from honey, sugar, jaggery, sugarcane, jam, glucose, etc. are readily absorbed and are to be avoided completely. Complex carbohydrates, such as cereals, whole grains, dals, pulses, sprouts, fruits and vegetables do not raise blood sugar quickly. Glycaemic index (GI) and glycaemic load (GL) both should be taken into consideration.

Proteins

The recommended dietary allowance (RDA) for protein is 1 gm/kg IBW. Pregnant women, lactating women and children require more protein compared to an adult in order to meet their physiological needs. Skimmed milk and milk products (except cream, butter), dals and pulses, nuts, oilseeds, fish, egg, poultry and meat are rich sources of protein. Cereals are fair sources of protein. For Type 1 diabetic children 1 to 1.5 gm protein/kg IBW is recommended. 'Lente' carbohydrate provides a good quality protein in addition to complex carbohydrate.

Fats

Fats are concentrated source of energy. Excess of fat in the diet increases the risk of obesity, and the process of atherosclerosis. Visible fats like ghee, butter, vanaspati contain a high proportion of saturated fats, which tend to increase serum cholesterol levels. Vegetable fats, such as sunflower oil, safflower oil, and corn oil contain a high proportion of polyunsaturated fatty acids (PUFA), which are helpful for controlling cholesterol levels. Some amount of n_3 to n_6 ratio of fat that is derived from milk and milk products, egg, flesh foods, nuts and oilseeds are known as invisible fats. A diabetic diet should provide both visible and invisible fat in limited quantities. A diabetic patient can take 15 to 20 gm visible fat per day to meet EFA requirement and maintain palatability of the diet.

Vitamins and minerals

They both are essential for the body. Cereals, pulses, dals, milk, dark green leafy vegetables, fresh fruits, egg and fish are common sources of these nutrients.

Fibre

Dietary fibre is beneficial in Type 2 DM as well as Type 1 DM. Fibre present in vegetables, certain fruits, legumes and fenugreek seeds (methi seeds) are soluble in nature and is effective in controlling blood sugar and serum lipid levels. Insoluble fibre present in cereals and millets like ragi, jowar and bajra provides bulk and roughage inducing satiety and improves long-term blood glucose tolerance.

Diet Plans

The diet plan is given in the **Table 2**.

The Glycaemic Index and Glycaemic Load

The glycaemic index (GI) is a numerical system of measuring how fast a carbohydrate triggers a rise in circulating blood sugar. Foods are tested and compared to the standard food glucose. The GI of glucose and white bread is set at 100.

$$GI = \frac{\text{Blood glucose area of test food}}{\text{Blood glucose area of reference food}} \times 100$$

A list of carbohydrates with their glycaemic values is shown below. A GI of 70 or more is high, a GI of 56 to 69 inclusive is medium, and a GI of 55 or less is low.

Food	Glycaemic index (GI)
Simple sugars	
Glucose	85 to 111
Honey	32 to 87
Sucrose	55 to 68
Fructose	12 to 25
Cereal products	
Whole wheat	67
Oat bran	42 to 75
White bread	67 to 87
Whole wheat bread	52 to 87
Corn flakes	80
Macaroni	64
Rolled oats	66
Puffed rice	132
Puffed wheat	110
White rice	50 to 64
Brown rice	66 to 87
Pulses	
Soya bean	15 to 20
Green peas, dried	39 to 54
Vegetables	
Sweet potato	44 to 78
Yam	74
Potato	74 to 97
Corn	37 to 62
Fruits	
Apple	39
Orange	35 to 51
Banana	46 to 70
Grapes	25
Raisins	56 to 60
Milk and milk products	
Ice cream	52
Yoghurt	14 to 23
Whole milk	11 to 40
Skim milk	32

The glycaemic load (GL), is a relatively new way to assess the impact of carbohydrate consumption. A GI value tells you only how rapidly a particular carbohydrate turns into sugar. It does not tell you how much of that carbohydrate is in

Table 2: Diet Plan in Diabetes Mellitus

Meals	1,400 Kcal	1,600 Kcal	1,800 Kcal	2,000 Kcal
Breakfast	1-cup tea with ½ cup skimmed milk (no sugar). 1 slice of whole wheat bread (without butter or cheese) (preferably in the form of a sandwich) *or* 2 dry phulkas *or* 2 dry khakhras *or* 2 idlis (without coconut chutney) *or* 1 cup cooked vegetable upma/ roasted rice flake chiwda/sundal.	1-cup tea with ½ cup skimmed milk (no sugar). 2 slices of whole wheat bread (without butter or cheese) (preferably in the form of a sandwich) *or* 2 dry phulkas *or* 2 dry khakhras *or* 2 idlis (without coconut chutney) *or* 1 cup cooked vegetable upma/ roasted rice flake chiwda/sundal.	1-cup tea with ½ cup skimmed milk (no sugar). 3 slices of whole wheat bread (without butter or cheese) (preferably in the form of a sandwich) *or* 3 dry phulkas *or* 3 dry khakhras *or* 3 idlis with ½ cup sambhar (without coconut chutney) *or* 1 cup unsweetened corn flakes *or* 2 dosas (made on a non-stick pan) with rasam *or* 1 cup cooked vegetable upma/sundal.	1-cup tea with ½ cup milk (no sugar). 3 slices of whole wheat bread (without butter or cheese) (preferably in the form of a sandwich) *or* 3 dry phulkas *or* 3 dry khakhras *or* 3 idlis with ½ cup sambhar (without coconut chutney) *or* 1½ cup unsweetened corn flakes *or* 2 dosas (made on a non-stick pan) with rasam *or* 1½ cup cooked vegetable upma/sundal.
Mid-morning	—	1-cup plain skimmed milk.	1-cup plain skimmed milk.	1-cup plain skimmed milk.
Lunch	1 bowl thoroughly washed raw vegetable salad/unseasoned vegetable soup 2 phulkas (without ghee).	1 bowl thoroughly washed raw vegetable salad/unseasoned vegetable soup 2 phulkas (without ghee). ½ cup cooked rice.	1 bowl thoroughly washed raw vegetable salad/unseasoned vegetable soup 3 phulkas (without ghee) ½ cup cooked rice.	1 bowl thoroughly washed raw vegetable salad/unseasoned vegetable soup 3 phulkas (without ghee) ½ cup cooked rice.
	¾ cup dal or 1 cup sambhar or ½ cup lean non-veg (non-fried, without skin) curry or ½ cup sundal. ½ cup cooked vegetables. ½ cup skimmed milk curds. Restrict use of coconut/peanuts, sugar, jaggery, and fried non-veg.	¾ cup dal or 1 cup sambhar or ½ cup lean non-veg (non-fried, without skin) curry or ½ cup sundal. ½ cup cooked vegetables. ½ cup skimmed milk curds. Restrict use of coconut/peanuts, sugar, jaggery, and fried non-veg.	¾ cup dal or 1 cup sambhar or ½ cup lean non-veg (non-fried, without skin) curry or ½ cup sundal. ½ cup cooked vegetables. ½ cup skimmed milk curds. Restrict use of coconut/peanuts, sugar, jaggery, and fried non-veg.	¾ cup dal or 1 cup sambhar or ½ cup lean non-veg (non-fried, without skin) curry or ½ cup sundal. ½ cup cooked vegetables. ½ cup skimmed milk curds. Restrict use of coconut/peanuts, sugar, jaggery, and fried non-veg.
Evening	1-cup tea with ½ cup skimmed milk (no sugar). 1 cup roasted rice puffs (no sev or puri) or 2 Marie biscuits.	1-cup tea with ½ cup skimmed milk (no sugar). 1 plain whole wheat bread (no butter or cheese) or ¾ cup roasted rice flakes (no nuts) or 1 cup roasted rice puffs or 4 Marie biscuits.	Same as breakfast (type and quantity)	Same as breakfast (type and quantity)
Dinner	Same quantity as lunch.	Same quantity as lunch.	Same quantity as lunch.	Same quantity as lunch.
Bed-time	1 medium fruit (except banana, chickoo, mango, custard apple).	1 medium fruit. (except banana, chickoo, mango, custard apple).	1-cup plain skimmed milk or 1 medium fruit (except banana, chickoo, mango, custard apple).	1-cup plain skimmed milk and 1 medium fruit (except banana, chickoo, mango, custard apple).
	Total oil for the days cooking 2 to 3 tsp.	Total oil for the days cooking 2 to 3 tsp.	Total oil for the days cooking 4 tsp.	Total oil allowance for the days cooking 4 tsp.

a serving of a particular food. The amount of available carbohydrate in a specific food serving multiplied by the GI value is called the glycaemic load (GL) value of the food. You need to know both things to understand a food's effect on blood sugar.

The carbohydrate in watermelon, for example, has a high GI. But there is not a lot of it, so watermelon's glycaemic load is relatively low.

A GL of 20 or more is high, a GL of 11 to 19 inclusive is medium, and a GL of 10 or less is low.

GOUT

A diet low in fat and purine is advised to decrease elevated blood uric acid levels. Before imposing dietary restriction, factors inhibiting the excretion of the accumulated uric acid should be excluded, e.g. presence of alcohol, excess tannins, fat. A thorough assessment of the diet by a registered dietician/ medical nutrition therapist will help in estimating the sources of purine in patient. Increased amounts of fluid will help excrete the accumulated uric acids.

Energy

It should be adjusted to 500 Kcal below the normal requirement for overweight/obese patients. Care should however be taken to avoid very low calorie diets (VLCD). Exercise helps weight reduction. However, strenuous exercise (weight bearing) should be avoided. Similarly, fasting/low carbohydrates should be avoided as it precipitates a gouty attack due to ketosis.

Carbohydrates

Liberal use of fruits and vegetables is recommended. Use of soluble fibre is particularly helpful.

Protein

Organ meats and legumes are best avoided due to their high purine content. Skimmed milk and its products should be used liberally to meet the protein requirements.

Fats

A low fat diet will promote weight reduction and relieve symptoms of gout by facilitating urinary excretion of accumulated uric acid.

Alcohol

Alcohol consumption should be completely avoided as it may inhibit urinary excretion of urates.

Fluid

Liberal fluid intake in the form of thin buttermilk, vegetable soups, etc. will facilitate urinary excretion of accumulated uric acid and also prevent formation of calculi. However, avoid cold drinks, carbonated beverages, large amounts/strong decoctions of tea and coffee.

Table 3 shows list of foods moderate to high in purine.

Table 3: List of Foods Moderate to High in Purine

Liver, kidney, shell fish, meat extracts – meat gravies, shrimp, sardine, soups with meat stock, chicken, ham, tuna fish, mushroom, mutton, crab, oyster, lobster
Whole milk, cream, ice cream, cheese
Sweetbread, bakers and brewer's yeast
Lentil, pulses
Cauliflower, peas, spinach, mushrooms, brinjal and sometimes cabbage
Chickoo and custard apple

PEPTIC ULCER

The diet for chronic peptic ulcer disease is designed to restrict foods or beverages that may cause gastric irritation and/or stimulate excessive gastric acid secretion. General recommendations for the diet are given in Table 4.

Table 4: General Recommendations for the Diet in Peptic Ulcer

Eat balanced meals in a day in a relaxed mood
Avoid too hot or too cold foods
Avoid spicy and strongly flavoured foods
Avoid alcohol, caffeine containing beverages, cigarette smoking and tobacco chewing, spearmints and peppermints
Good physical and emotional rest is essential
Avoid fried foods

Principles of Diet

Energy

Energy of 35 to 40 Kcals/kg is recommended, as these patients are generally malnourished due to the 'so called' dietary restriction. Malnutrition affects the rapidly dividing cells of the GIT and could affect healing.

Proteins

Proteins have a buffering effect. Milk proteins are considered better compared to non-vegetarian foods as they do not irritate gastric mucosa or stimulate acid secretion. A good amount of protein in the range of 1.2 gm/kg IBW should be provided.

Carbohydrates

Adequate amounts of simple carbohydrates should be given. Avoid food items with fibres. Soluble fibres should be encouraged to meet the daily fibre requirements.

Fats

Fats delay gastric emptying and also help in meeting the caloric requirement. Fats from fried snacks and sweets may be avoided, as they are difficult to digest, may cause nausea and aggravate the symptoms.

Vitamins and minerals

Deficiency may occur with self-imposed limitation of green leafy vegetables and other foods. Adequate vitamin C and iron is necessary for proper healing of ulcer.

Fibre

Fibrous foods, such as raw vegetables, leafy vegetables, fruits (with peel), irritate mucosal lining. Thus only soft cooked vegetables and fruits are allowed during flare-ups.

pH of food

Most foods are considerably less acidic than the inherent gastric pH. Therefore pH of a food prior to ingestion has little therapeutic implication except for patients with lesions of mouth/oesophagus.

Alcohol

Alcohol consumption causes mucosal lining damage and may worsen existing disease/interfere with the treatment of peptic ulcer.

Miscellaneous

Stimulants, e.g. coffee, caffeine, spices, stimulate acid secretion and may also reduce lower oesophageal sphincter pressure. Some bland diet may do well in acute flare-up.

Aroma of cooked foods also stimulates acid secretion. Thus cooked food should be bland in taste and flavour. Spices, condiments, pickles, vinegar, chillies, garlic and onions are not permitted in the diet.

LIVER DISEASES

The diet advised must provide adequate calories and essential nutrients, including essential amino acids to prevent malnutrition and extensive liver damage.

Diet in Infective Hepatitis

A high protein, high carbohydrate, moderate fat diet is recommended.

Carbohydrates

Simple carbohydrates given in large quantities improve liver function by building adequate hepatic glycogen stores and prevent endogenous protein breakdown by their protein-sparing effect.

Protein

High protein diet helps to regenerate liver cells. 1.0 to 1.2 gms/day is allowed in mild jaundice. Proteins may be restricted in decompensated liver disease and in case of increased conjugated bilirubin.

Fats

Fats make food palatable and also help to meet the essential fatty acid requirements. Fried foods may cause nausea.

Vitamins and minerals

Supplementation may be necessary to prevent imbalances.

Miscellaneous

Alcohol should be avoided, as it is directly hepatotoxic.

Utmost hygienic condition should be observed in preparing and handling food.

Cirrhosis of Liver

It is important to consider the dry body weight of patient while calculating nutrient requirements.

A high carbohydrate diet, moderate to high proteins (1.0 to 1.2 gm/kg dry body weight) carefully watching for signs of hepatic encephalopathy, moderate fats with supplementation of vitamins and minerals is recommended.

HYPERTENSION

Principles of diet are same as in healthy adult except for sodium restriction. An average Indian diet contains 10 to 15 gm of salt. Salt should be restricted to 4 to 5 gm/day as per follows:

Guidelines for a Low Salt Diet

Avoid using salt at the table. Do not add salt in chapatti, rice, curd, and salads. The diet can be made palatable by judicious use of garlic, ginger, mint, lemon, vinegar, jeera powder, mustard and black pepper. Low sodium salts are high in potassium and may be beneficial but should be used carefully in patients with an underlying renal problem.

List of Foods High in Sodium

Dairy products: butter, cheese, ice creams, etc.

Ready to eat food items: canned foods, sauces, chutneys, ketchup, papad, pickles, salad dressings, mayonnaise, etc.

Fried foods: chips, wafers, sev, chiwda and other fried snacks.

Bakery products: salted biscuits, cakes, pastries, bread rolls, and khari biscuits

Non-veg items: shellfish, dry fish, fried non-veg, non-veg gravies and organ meats.

Baking powder, Ajinomoto.

Salt restriction may not be compulsory for the patients receiving diuretic therapy.

DASH diets (Dietary Approaches to Stop Hypertension) recommend the use of 5 to 7 servings of fruits and vegetables and helps by providing roughage, vitamins, minerals, and anti-oxidants.

ISCHAEMIC HEART DISEASE

Principles of Diet

Carbohydrates

Simple carbohydrates should be avoided as they contribute towards endogenous production of cholesterol and triglycerides.

Energy

Weight reduction/achieving IBW with a low calorie diet helps to relieve the extra burden on heart.

Proteins

A normal intake of 1 to 1.2 gm/kg IBW is suggested. Animal proteins should be best avoided/used judiciously with restrictions due to their high cholesterol content.

Fats

Fat content should be restricted to lower the serum cholesterol levels. A vegetarian diet is helpful as it is low in fat, cholesterol and high in fibre.

Rich sources of cholesterol

Butter, cheese, cream, ghee, egg yolk, liver, red meats.

Poor sources of cholesterol

Egg white, fish, lean cuts of chicken, skimmed milk, cottage cheese (prepared from skimmed milk), vegetable oils, fruits, vegetables, whole grains.

Role of PUFA have been identified in prevention of heart disease. It is important to obtain right amount of different fatty acids in the diet and avoid excessive intake of any one kind. The desirable polyunsaturated fatty acids/saturated fatty acids (PUFA/SFA) ratio is about 0.8 to 1.0. **Table 5** gives PUFA/SFA ratio of common fats.

Although the ratio of PUFA:MUFA:SFA is controversial, the latest recommendation is 1:1.5:1.

Table 5: Ratio of Polyunsaturated Fatty Acids to Saturated Fatty Acids of Common Fats

Oil	PUFA/SFA ratio
Safflower oil	8.2
Sunflower oil	6.4
Corn oil	4.46
Soybean oil	4.07
Cotton-seed oil	1.96
Sesame oil	2.66
Peanut oil	1.82
Coconut oil	0.04
Butter	0.06

RENAL DISEASES

Diet plays a central role in the management of kidney diseases.

Principles of Diet in Glomerulonephritis

In acute stages, an effort should be made to maintain fluid and electrolyte balance and provide sufficient non-protein calories.

Energy

Poor appetite may interfere with energy intake. The calorie intake can be increased up to RDA by use of jellies, sugar, butter, oil, desserts, etc. using the allotted amount of protein sources.

Carbohydrates

Simple carbohydrate diet like fruit juices with glucose, sweetened tea, etc. should constitute the main bulk of calories. Excessive sweets may however cause nausea.

Protein

Unless oliguria or renal failure develops, proteins are not restricted. Proteins are to counteract the loss of albumin in case albuminuria exists. The emphasis is upon proteins of high biological value especially egg and milk. The limitation placed on second-class protein needs restriction of dals, pulses, nuts, beans which are otherwise good sources of calories also.

Fats

Normal quantities are allowed as excretion of their end products do not depend on kidney function.

Sodium

Sodium restriction to 1,000 mg is necessary with existing oedema, hypertension or oliguria.

Fluid

In oliguria, fluids are restricted to prevent further oedema. Allowance depends on the hydration levels, previous day's urine output, fever, vomiting, diarrhoea and high environmental temperature.

Diet in Chronic Renal Failure (Conservative Management)

Efforts should be made to reduce the nitrogenous waste load on the kidneys. Knowledge of the usual dry body weight and proper assessment of the actual food quantity consumed by an experienced medical nutrition therapist is of utmost importance. Additionally, a good psychological and emotional support goes a long way in improving QOL. A summary of diet in various diseases is given in **Table 6**.

Goals of Nutrition Care in the Management of ESRD

- To prevent deficiency and maintain good nutrition status and growth, in cases of children through adequate protein, energy, vitamin and mineral intake.
- To control oedema and electrolyte imbalances by controlling sodium, potassium and fluid intake.
- To prevent/retard the development of renal osteodystrophy by controlling calcium, phosphorus and vitamin D intake.
- To enable the patient to eat a palatable, attractive diet that fits his/her lifestyle as much as possible; thereby improving QOL.

Energy

35 to 40 Kcals/kg dry present body weight; wherein carbohydrates and fats form the bulk. Non-protein cereals like arrowroot, sago, root-vegetables like potato, sweet potato, help to meet the requirement of non-protein, high-energy food items.

Proteins

Protein intake of 0.7 to 0.8 g/kg present dry body weight ensures meeting the patient's requirement of daily basis. Reducing the protein further than this actually raises the serum creatinine levels due to tissue catabolism. Major amounts/portions of protein allowances should come from first class proteins (FCP), sources of which include milk and milk products, egg and non-vegetarian food items.

Fats

Moderate amounts of fat will give palatability and also add calories, in addition to meeting the EFA requirements.

Sodium

Salt restriction of 2 to 3 gm is usually recommended to maintain the electrolyte balance. Higher amounts may further aggravate hypertensive nephropathy changes.

Potassium

Moderate potassium in the diet, in the range of 1,500 to 2,000 mg, is allowed. High potassium obtained through fruit juices, coconut water, etc. may cause cardiac arrhythmias. Salts that are otherwise high in potassium should be avoided.

Fluid

Allowance depends on the hydration levels, previous day's urine output, fever, vomiting, diarrhoea and high environmental temperature.

Enteral nutrition

Enteral nutrition consists of provision of nutrients through a tube when oral intake is inadequate, for the purpose of maintaining or restoring nutrients status. It is given to all patients with 'functioning GI tract' who are unable to consume adequate amount of nutrients orally to meet their nutritional requirements.

PRINCIPAL GOALS OF NUTRITION SUPPORT

- This is to support protein synthesis rather than suppress proteolysis. This will help to initiate the anabolic phase leading to patient's convalescence.
- Understand the body's metabolic response to injury and illness.
- Assess the nutritional status of the patient in order to decide whether nutritional intervention is indicated.
- Determine the optimal route of nutrient intake.
- Provide substrate (carbohydrates, proteins, fats, vitamins and minerals) for the ongoing metabolic functions.
- Limit catabolism and maximise protein synthesis.
- Bolster immune function and improve wound healing.
- Improve cardiac and respiratory function by restoring glycogen stores in the cardiac and diaphragmatic muscles.
- Correct acid-base and electrolyte disturbances.
- Potentially modify the systemic inflammatory response.
- Be aware of, anticipate and minimise feeding (technique of delivery and metabolic) related complications.
- Understand the ability of total parenteral nutrition to serve as a drug vehicle and to help in the correction of metabolic derangements.
- Confirm adequacy of nutrition support and response to support.

Although it is not known how long a hyper-metabolic patient can tolerate starvation, the loss of lean tissue that occurs in catabolic patients (20 to 40 gm N_2) suggests that depletion to a critical level may occur in 7 days.

The need for nutrition support is based on current status of the patient's nutritional reserves and an estimate of the associated stress/severity of the underlying disease, with a heightened systemic response. Anticipated time delay before which the patient can resume feeds/normal diet.

Nutritional Supplements

It may not be always possible to meet the nutritional requirements of a patient, especially if the nutritional intake is poor or the catabolism is high. Artificial nutritional supplements

available in the market are of great help during these times. There are a wide variety of disease specific nutritional supplements available. Carbohydrates may be provided as simple sugars or complex carbohydrates such as fibre. Most proprietary formulae are lactose and gluten free. Nutrition support in critically ill patients is aimed at preventing the negative effects of starvation during the course of disease and at minimising the negative effects of protein catabolism. Healthy, malnourished non-septic patients utilise mainly carbohydrates for energy production and convert excess glucose into fat. In contrast, patients with sepsis show an increase in oxygen consumption and utilise mainly stored fat to meet their energy requirements. The same effects are seen in a non-septic critically ill patient. Consequently, it is recommended that the portion of fats in artificial nutrition be increased for patients with either sepsis or non-septic critical illness. Care is taken to avoid essential fatty acid deficiency. Studies show that the peptide system is less affected than the free amino acid pathway in malnourished patients. Administration of peptides can thus prevent protein deficiency. Furthermore, due to the lower osmolality, peptide based formulas are better tolerated than amino acids. Trace elements, vitamins and minerals are also added in doses equivalent to RDA. Many supplements are available with immune boosters like glutamine and arginine.

In stress or catabolic states, a high protein, moderate carbohydrate, moderate fat with immuno-modulators is required.

Table 6: Diet in Various Diseases

Disease condition	Energy (Kcals)	Carbohydrate (gm)	Proteins (gm)	Fats (gm)	Fibre (gm)	Salt (mg)	Exercise
Obesity	20 Kcals/kg IBW, not <1,000 Kcals/day	60 to 65% more of complex carbohydrates Avoid simple sugars	15 to 20%	15 to 20% Maintain EFA	15 to 20 gms/ 1,000 Kcals	Preferably restricted	Must
Diabetes mellitus	25 to 30 Kcals/kg IBW	55 to 60% more of complex carbohydrates Avoid simple sugars	15 to 20%	15 to 20% Maintain EFA PUFA:MUFA: SFA = 1:1.5:1	15 to 20 gms/ 1,000 Kcals	—	Must
Peptic ulcer	35 to 40 Kcals/kg IBW	65 to 70% more of simple carbohydrates Avoid complex sugars	1.2 to 1.5 gm/kg IBW	Moderate	Avoid roughage Softly cooked vegetables and peeled fruits (non citrus)	Avoid salty, spicy, processed, canned foods	—
Gout	weight reduction to IBW desired, 25 Kcals/kg IBW	60 to 65% more of complex carbohydrates Avoid simple sugars Very low CHO = ketosis = worsening of gout	1.2 to 1.5 gm/kg IBW Avoid Non-vegetarian food sources	Low fat facilitates urinary excretion of urates	High	—	Helps achieve IBW. Excess aggravates attack
Hypertension	25 Kcals/kg IBW	60 to 65% more of complex carbohydrates Avoid simple sugars	1 to 1.2 gm/kg IBW Choose lean meat	15 to 20% Maintain EFA PUFA: MUFA: SFA = 1:1.5:1	15 to 20 gm/ 1,000 Kcals 'DASH' diets are beneficial	4 to 5 gm/day	Helpful
IHD	25 Kcals/kg IBW	60 to 65% more of complex carbohydrates Avoid simple sugars	1 to 1.2 gm/kg IBW Choose lean meat	15 to 20% Maintain EFA PUFA: MUFA: SFA = 1:1.5:1 n3:n6 = 5 to 7:1 Cholesterol <300 mg/dL	15 to 20 gm/ 1,000 Kcals 'DASH' diets are beneficial	4 to 5 gm/dL More severe in CCF	Helpful
Jaundice	35 to 40 Kcals/kg IBW	65 to 70% more of simple carbohydrates Avoid complex sugars	1.2 to 1.5 gm/kg IBW	Moderate	Avoid roughage Softly cooked vegetables and peeled fruits (non citrus)	No restriction required	Adequate rest required
Cirrhosis of liver	35 to 40 Kcals/kg Dry body weight	65 to 70% more of simple carbohydrates Avoid complex sugars	1.2 to 1.5 gm/kg dry body weight Watch for impeding signs of cirrhosis	Moderate	Avoid roughage Softly cooked vegetables and peeled fruits (non citrus)	2 to 3 gm/day	—
ESRD	35 to 40 Kcals/ Dry body weight	65 to 70% more of simple carbohydrates Avoid complex sugars	0.8 gm/kg dry body weight	Moderate to high for palatabilty and EFA requirements	Moderate	2 to 3 gm, depending on the oedema and control of HTN	—

28.5 Care of Terminally Ill

Anil Chaturvedi

"Getting well is not the only goal.
Even more important is learning to live without fear,
To be at peace with life, and ultimately death".

– Bernie Siegel, MD

INTRODUCTION

Care of terminally-ill is care beyond cure. When a patient will no longer respond to curative treatment and is considered to have a terminal illness, it becomes the responsibility of those who care for him/her to ensure that the patient is helped to live the remaining life as fully as possible. This means that we should use all our available resources to relieve the patient's suffering and promote his/her well-being. The patient's time is limited and we must deliver effective, high quality care first time around; we cannot get it right the next time.

To ensure death with dignity, patients need holistic care. Physical, social, emotional, practical, and spiritual needs must be met. Holistic care demands time, attention and skills from nursing staff, who in turn must be supported to give this care. Terminal illness is not only a medical problem, but it has moral, ethical, legal, social, cultural and spiritual dimensions.

Terminal illness is defined as:

- Such illness, injury or degeneration of physical or mental condition, which is causing extreme pain and suffering to the patient and which, according to reasonable medical opinion, will inevitably cause the untimely death of the patient concerned, or
- Which has caused a persistent and irreversible vegetative condition, under which no meaningful existence of life is possible for the patient.

Patients and their families are clear about what they want and need from the health care system at the end of life: freedom from distressing symptoms, such as pain and dyspnoea; the opportunity to communicate with physicians and others about death and dying; and the knowledge that they will be attended to and comforted by their physicians as they approach death. These goals are focussed on improving the quality of life of people living with a serious, chronic and life-threatening illness, irrespective of prognosis. Palliative care can be provided at any stage of illness and should be provided, in particular, simultaneously with all other appropriate medical treatments. Patients approaching the end of life certainly need palliative care but so do other patients who have acute exacerbations of chronic illness, such as heart failure, chronic obstructive pulmonary disease (COPD), cirrhosis, dementia, and cancer.

Palliative care is defined as 'the active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms and of psychological, social and spiritual problems is paramount. Common physical and psychological symptoms are outlined in **Table 1**. The goal of palliative care is achievement of the best possible quality of life for patients and their families'. Although palliative care has emerged as a recognised subspeciality, primary care physicians and their patients are eager to maintain strong relationships at the end of life which emphasise more than just the patient's disease. Therefore, it is imperative for physicians to equip themselves 'with the necessary information' and training in order to ensure their patients a 'good' death to the best of their ability. Palliative care is both an art and a science. The clinical course in the last days of terminally-ill patients is shown in **Figure 1**.

BASIC PRINCIPLES OF PALLIATIVE CARE

- Affirms life.
- Regards dying as a normal process.
- Neither hastens nor postpones death.
- Relieves pain and other symptoms.
- Integrates medical, psychological, and spiritual aspects of care.
- Offers a support system to patients and families.

All people have goals and hopes, and enjoy having control over their lives. Over time, each person develops a very personal sense of what brings greatest meaning and value and adds most to his or her quality of life. People in the hospital often feel that they are losing control. As their illness progresses, their goals and hopes may change. It is the physician's role to communicate with the patient and family, clarify their goals and priorities, and develop a plan of care based on this information. Regular reassessment of goals and priorities ensures that the patient, family, physician, and health care team are working together to maximise the patient's quality of life.

Table 1: Common Physical and Psychological Symptoms of Terminally-Ill Patients

Physical Symptoms	Psychological Symptoms
Pain	Anxiety
Fatigue and weakness	Depression
Dyspnoea	Hopelessness
Insomnia	Meaninglessness
Dry mouth	Irritability
Anorexia	Impaired concentration
Nausea and vomiting	Confusion
Constipation	Delirium
Cough	
Swelling of arms or legs	
Itching	
Diarrhoea	
Dysphagia	
Dizziness	
Loss of libido	
Faecal and urinary incontinence	
Numbness/tingling in hands/feet	

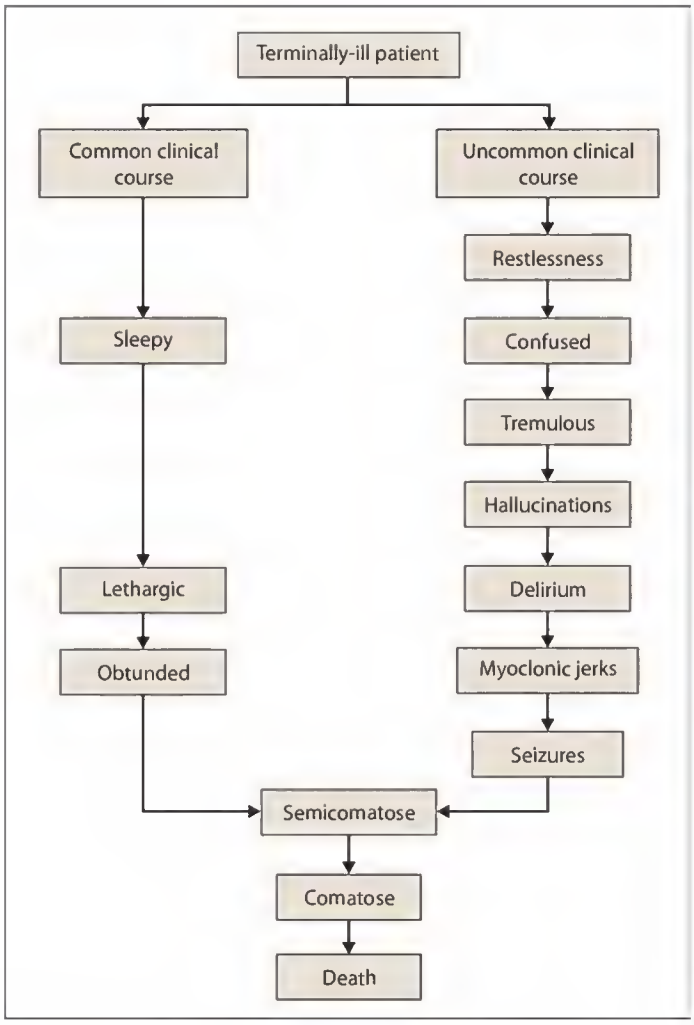

Figure 1: Clinical courses in the last days of terminally-ill patients.

Some potential goals of care are listed in **Table 2** and negotiating these goals are mentioned in **Table 3**. Historically, there has been a dichotomous division of goals of care, with a primary focus on curing illness rather than on relieving suffering in the dying patient.

Table 2: Potential Goals of Care

Cure of disease
Avoidance of premature death
Maintenance or improvement of function
Prolongation of life
Relief of suffering
Optimised quality of life
Maintenance of control
A peaceful death
Support for family and loved ones

Table 3: Seven Steps in Negotiating Goals of Care

Create the right setting
Determine what the patient and family know
Explore what they are expecting or hoping for
Suggest realistic goals
Respond empathetically
Make a plan and follow it through
Review and revise periodically, as appropriate

Medical Management at the End of Life

'Medical treatment' means treatment intended to sustain, restore or replace vital functions which, when applied to a patient suffering from terminal illness, would serve only to prolong the process of dying and includes:

- Life-sustaining treatment by way of surgery or administration of medicine or any other medical procedure; and
- Use of mechanical or artificial means, such as ventilation, artificial nutrition and hydration, and cardiopulmonary resuscitation.

ARTIFICIAL NUTRITION AND HYDRATION

Ceasing to eat and drink is a normal part of dying, not its cause. Understandably, families often become distressed when their loved one refuses food, at least in part because feeding has great cultural significance. Families often request artificial nutrition and hydration in the mistaken hope that it will prolong life, promote comfort, or improve functional status and quality of life. Unlike in the setting of acute illness, where these interventions may play an important role in recovery, in end-stage dementia, stroke, and cancer, artificial nutrition and hydration typically do not confer clinical benefit and may pose risks. For patients who are dying imminently, minimising fluids may increase comfort by preventing and reducing pulmonary and peripheral oedema, pleural effusions, ascites, and death rattle. Physicians play an important role in helping families understand the appropriate role of artificial nutrition and hydration. They may also direct families away from feeding and toward more productive actions that promote patient comfort, such as moistening the mouth with a swab or putting petroleum jelly on dry lips.

IMMINENT DEATH

As patients approach the final 24 to 48 hours of life, families may notice changes that, although normal, can be distressing if left unexplained. In addition to developing death rattle or dry mouth, patients may have Cheyne-Stokes breathing pattern, irregular breathing or slow and gasping respirations. Breathing may pause for as long as 20 to 30 seconds. Urine output may fall, especially if patients are not drinking and not receiving artificial hydration, and patients may become incontinent of urine and stool. The extremities typically become cold, mottled, blue, and swollen. In all cases, gentle reassurance that the changes family is witnessing are a normal part of dying, can ameliorate anxiety and fear. It can be comforting for families to know that physicians are aware of and anticipating these changes, and watching for specific signs and symptoms can assist clinicians with prognosis.

PSYCHOLOGICAL SUPPORT AND SPIRITUAL ISSUES

The experience of the end of life encompasses the psychologic, social, spiritual, and physiologic state of a patient. Providing comprehensive care to dying patients demands that physicians attend to these issues, in addition to relieving distressing physical symptoms.

COMMUNICATION

Being available to take calls and to answer questions from the patient and family provides a comfort and a confidence all its own. Be open. Be honest. Be available. Have a well thought-out, agreed-on, and

documented plan of care so that the patient, family, other health care providers, and covering physicians know what to expect and how to manage any changes in the patient's symptoms or status.

COMMUNICATING WITH RELATIVES

When a patient is terminally-ill, his or her relatives will need support, information and counselling. Meeting the needs of relatives can help to promote good communication between the patient and their family, thus improving the patient's psychological well-being.

Relatives express the need to:

- Be with the dying patient.
- Help to care for the dying patient.
- Be reassured that the dying patient is receiving good professional care.
- Be informed of diagnosis, treatment and prognosis. Information should be regularly updated.
- Discuss and plan care of the patient if the patient is to be discharged.
- Be informed of the patient's impending death if this is thought to be imminent.
- Have comfort and support from other relatives and friends.
- Have opportunities for rest, sleep and facilities for washing and changing, meals.
- Have adequate privacy.
- Receive spiritual support from appropriate sources, if required.
- Receive support and acceptance from ward staff.

CONCLUSIONS

Physicians do care for dying patients. There is much that physicians can do to provide high-quality care to patients approaching the end of life. By providing expert symptom management; discussing issues, such as prognosis and death, sensitively, compassionately, and providing emotional, spiritual, psychological, and social support, physicians can provide dignity and comfort to the dying.

"This little life is all we must endure,
The grave's most holy peace is ever sure,
We fall asleep and never wake again;
Nothing is of us but the mouldering flesh
Whose elements dissolve and merge afresh
In earth, air, water, plants, and other men".

– James Thomson

28.6 Exercise and Yoga in Health and Disease

S Dwivedi, Shiva Narang

Exercise and yoga both are essentially lifestyle related activities which enhance the physical, mental and spiritual development of an individual in a complimentary way. Exercise is a physical activity that is planned, structured, repetitive, and is meant for conditioning of any part of the body, while yoga is conceptualised as a way of life consisting of certain regulatory principles, breathing exercises, physical postures, and meditation. Exercise is dominantly utilised to improve health and maintain fitness while yoga is considered to enhance mental ability and additionally has some therapeutic potential in certain psychosomatic disorders.

HISTORY

The benefits of exercise have been known since antiquity. However, it was Morris (1953) who first conclusively proved the link between heart disease, physical health and exercise (or lack of it). He noted that men of similar social class and occupation (bus conductors versus bus drivers) had markedly different rates of heart attacks, depending on the level of activity. Bus drivers, by and large, having sedentary occupation had a higher incidence of heart disease, while bus conductors always on the move had a lower incidence. This was a landmark in study proving the link between physical activity and coronary heart disease and was later confirmed by many studies.

FORMS OF EXERCISE

Exercise can be categorised as follows: short-term maximal exercise, such as sprinting or climbing stairs; endurance exercise, such as running or walking for long distances and progressive increases in exercise until maximal capacity is reached. Types of exercise include isometric and isotonic (aerobic) exercise. In isometric exercises, the exercise is done against resistance, for example weight lifting, pushing or pulling. In isotonic exercise, there is increased oxygen consumption by exercising muscle. These are good for cardiovascular fitness and examples are walking, running, cycling and swimming.

ADVANTAGES OF EXERCISE IN HEALTH AND DISEASE

- Strengthening muscles
- Ensuring cardiovascular fitness
- Honing athletic skills
- Achieving/maintaining weight loss
- Boosting immune system
- Prevention of coronary artery disease (CAD), hypertension, Type 2 diabetes (T2DM) and obesity
- Management of CAD, hypertension, T2DM, obesity, musculoskeletal disease, anxiety, depression, etc.

BENEFITS OF EXERCISE IN HEALTH AND DISEASE

There are large numbers of physiological benefits of exercise, such as improvement in muscular function, strength and improvement in the body's ability to take and use oxygen. As one's ability to transport and use oxygen improves, regular daily activities can be performed with less fatigue. This is particularly important for patients with cardiovascular disease, whose exercise capacity is typically lower than that of healthy individuals. There is also evidence that exercise training improves the capacity of the blood vessels to dilate in response to exercise or hormones, consistent with better vascular wall function and an improved ability to provide oxygen to the muscles during exercise. Studies measuring muscular strength and flexibility before and after exercise programmes suggest that there are improvements in bone health and ability to perform daily activities, as well as less likelihood of developing back pain and disability, particularly in older age groups.

Benefits of regular exercise on cardiovascular health include increase in exercise tolerance; reduction in body weight, blood pressure, LDL and total cholesterol and concurrent increase in HDL-cholesterol and insulin sensitivity. Recent observational data from the Nurses' Health Study and the Women's Health Study have demonstrated similar relationships among physical activity, exercise, fitness, and outcome for women. It is said that even a small amount of exercise is cardio-protective.

Manson *et al* suggest that an hour per day of moderately intense exercise is closer to optimal, and most evidence suggests that progressive amounts of exercise lead to a progressive reduction in cardiac risk. A meta-analysis of 30 cohort studies involving more than 2 million person-years of observation demonstrates a nearly linear decline in the risk of CAD with increasing levels of physical activity.

There is also evidence that moderate weight loss normalises fasting hyperglycaemia in patients with poorly controlled T2DM. The Finnish Diabetes Prevention Group and Diabetes Prevention Program (DPP) have revealed that a low fat, low calorie diet and moderate exercise reduces the risk of developing T2DM by almost 58%.

Exercise also plays an important role in the management of certain musculoskeletal diseases, such as ankylosing spondylitis, fibromyalgia and osteoarthritis by maintaining mobility and avoiding deformity.

Recent reports also suggest that regular physical activity relieves symptoms of depression, anxiety and improves mood. Regular physical activity may reduce the risk of developing depression.

As effects of exercise on blood pressure, glucose levels, and lipids are, in part, acute effects of recent exercise, it is advised that people should try to exercise daily to minimise the number of days missed. The Center for Disease Control and Prevention and the American College of Sports Medicine recommend at least 30 minutes of moderately intense physical activity on most, and preferably all days of the week.

LIMITATIONS OF EXERCISE

Fatiguability, repetitive nature, and loss of motivation are the main drawbacks. There is a transient increase in the risk of developing cardiac-related complications (for example, a heart attack or serious heart rhythm disorder) during exercise. However, this risk is extremely small. For adults without existing heart disease, the risk of a cardiac event or complication is estimated to be one in 4,00,000 to 8,00,000 hours of exercise. The scope of exercise is also limited in disease states.

We shall now move on to yoga, which is an ancient practice having wide utility both in health and disease.

YOGA

Yoga is a healing system practised for more than 5,000 years. The first Hindu teacher to actively advocate and disseminate various aspects of Yoga to a Western audience was Swami Vivekananda, who toured Europe and the United States in the 1890s. The word 'yoga' comes from the Sanskrit word *yuj*, which means 'yoke or union' implying a union between the mind and the body. Patanjali, the exponent of yoga defined it as hindering of wavering mind. It is essentially based on mind and body relationship aiming complete 'homeostasis' between the two through eight steps; namely *yama* (moral behaviour), *niyama* (healthy habits), *asana* (physical postures), *pranayama* (breathing exercises), *pratyahara* (sense withdrawal), *dharana* (concentration), *dhyana* (contemplation) and *samadhi* (higher consciousness) (**Figure 1**). Yoga in its pragmatic form combines healthy habits with physical postures, breathing exercises and meditation.

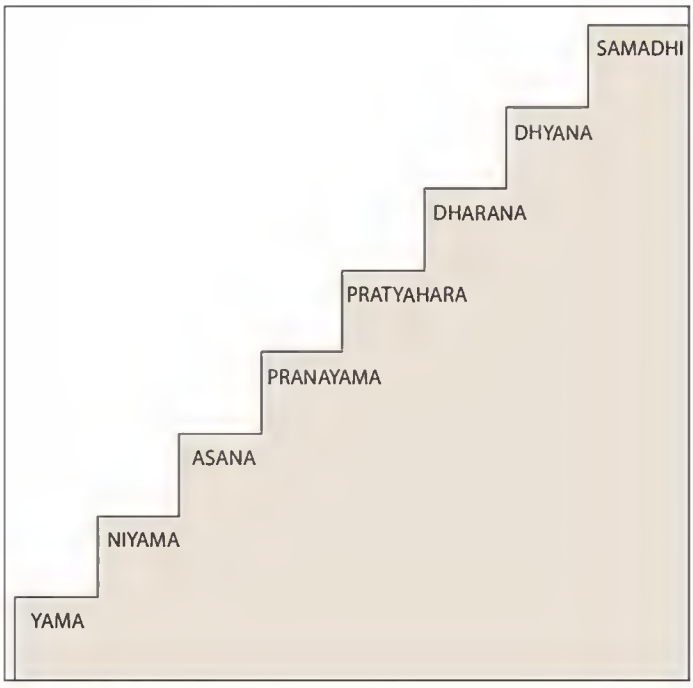

Figure 1: Stages of yoga.

The benefits of healthy habits, various physical postures, breathing exercises and meditation are now being intensively investigated and rationalised. Yogic exercises create awareness regarding body postures, alignment and patterns of movement. These asanas (physical postures) make body more flexible and help individuals to relax, even in a stressful environment.

Yoga has been basically used as part of general health regimen to achieve physical fitness, spiritual development, and relaxation. It has also been recommended for a variety of disease conditions including anxiety disorders or stress, depression, asthma, hypertension, diabetes and CAD.

Advantages of Yoga in Health and Disease

- Reduction in heart rate and blood pressure
- Increase in lung capacity
- Improved muscle relaxation
- Improvement in overall physical fitness, strength, and flexibility
- Positive change in levels of certain brain or blood chemicals
- Useful in treatment of CAD, hypertension, T2DM, thyrotoxicosis, anxiety neurosis, acid peptic disease, irritable bowel syndrome, and ulcerative colitis.

Yoga—role in various disease

Yoga has a definite complementary role in treatment of various disorders like CAD, hypertension, thyrotoxicosis, T2DM, anxiety neurosis, acid peptic disease, irritable bowel syndrome and ulcerative colitis. It has been demonstrated to help control hypertension and diabetes mellitus. Beneficial effects of yoga, particularly *shavashana* (corpse posture) and *pranayam* (regulated breathing exercises) on mild hypertension have been well documented. Similarly, regular yogic exercises (asanas) like *suryanamskar* (sun salutation postures), *tadasan* (mountain posture), *trikonasan*, (triangle posture), *padmasan* (lotus posture), *pranayam* (regulated breathing exercises), *paschimottanasan* (seated forward bend posture), *ardhmatsyendrasan* (half spinal twist posture), *pavanmukthasan* (wind removing postures), *sarpasan* (cobra posture) and *shavasan* (corpse posture) alongwith modern drugs have been found to lower fasting and postprandial blood glucose levels with lower dosage requirement of oral hypoglycaemic drugs. Yogic exercises have also been found to be useful for maintaining good glycaemic status for long periods of time. It has been suggested that yogic practices have a positive role in the prevention of diabetes. Besides hypertension and diabetes, life style modifications and stress management based on yogic principles mainly meditation, *shavashana* (corpse posture) *and pranayam* (regulated breathing exercises) have been advocated to reverse the process of CAD.

Limitations of Yoga

Yogic exercises are generally considered to be safe in healthy people when practiced appropriately. Studies have found it to be well tolerated, with few side effects. However, people with certain medical conditions should not use some yoga practises. For example, people with disc disease of the spine, extremely high or low blood pressure, glaucoma, retinal detachment, risk of blood clots, ear problems, severe osteoporosis, or cervical spondylitis should avoid some inverted poses. Although yoga during pregnancy is safe, it should be practiced under expert guidance.

28.7 Adult Immunisation

RK Singal, AK Agarwal

Immunisation is a well-established practise in the paediatric age group. However, it has not received the same attention in adults. The dynamic nature of adult immunisation is evident from the continuous development of new vaccines, new indications and new dosing schedules. The emergence of H1N1 influenza, and of a vaccine for its prevention, underlines the need to remain constantly updated in this field.

TETANUS

In the absence of effective treatment, immunisation is the preferred method for tetanus prevention. All adults who have previously not been immunised against tetanus should be given a full course of immunisation. All pregnant women must be immunised.

Two new tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccines (Tdap) are available for adults. These include [i] Adacel® that contains tetanus toxoid, diphtheria toxoid, and five pertussis antigens and [ii] Boostrix® that contains tetanus toxoid, diphtheria toxoid, and three pertussis antigens. The vaccine is administered as a 0.5 ml intramuscular injection in the deltoid.

Tetanus immunoglobulin (Tetglob™, Bharat Serums, Mumbai, India) provides passive protection. It is administered as a deep intramuscular injection in a dose of 250 IU. The recommended schedule for immunisation is shown in **Table 1** and the schedule for a person who has sustained a wound is shown in **Table 2**.

Table 1: Tetanus Immunisation Schedule

Group	Schedule
18 to 64 years, Childhood immunisation complete	Booster dose of Td or Tdap vaccine once in 10 years till the age of 65
>18 years, not immunised	Three doses of Td or Tdap. First two doses four weeks apart, third dose 6 to 12 months after second dose
Health care workers in contact with the patient	Single dose of Tdap vaccine, if >2 years since last dose
Women planning pregnancy	One dose of Tdap, if not received previously
Pregnant women who received Td >10 years ago	One dose of Td vaccine in the second or third trimester
Pregnant women who received Td 2 to 10 years ago	One dose of Tdap in the immediate postpartum period
Pregnant women never immunised	Three doses of Td in the second or third trimester; first two doses at least 4 weeks apart, third dose 6 to 12 months after second dose

Td = Tetanus toxoid, diptheria; Tdap = Tetanus toxoide, diphtheria, acellular pertussis.

Local reactions (generally erythema and induration with or without tenderness) are common after immunisation. Rare cases of Guillain-Barre syndrome have been reported after immunisation. A previous history of neurological illness, especially Guillain-Barre syndrome following administration of another vaccine, is a contraindication for immunisation.

Table 2: Tetanus Immunisation Schedule for Adults Sustaining a Wound

History of Tetanus Toxoid Doses	Clean Minor Wound	All Other Wounds
Unknown or less than three doses	Tdap/Td	Tdap/Td, TIG
Three or more doses	Tdap/Td if more than 10 years elapsed since last tetanus toxoid dose	Tdap/Td if more than 5 years have elapsed since the last tetanus toxoid dose

TIG = Tetanus immunoglobulin; Tdap = Tetanus toxoid, diphtheria, acellular pertussis; Td = Tetanus toxoid, diphtheria.

RABIES

With a large population of unvaccinated stray dogs, rabies continues to be prevalent in India. The fact that no treatment is available for established disease and a fatal outcome is universal, highlights the importance of immunisation, the only effective preventive measure. The spread of rabies can best be prevented at a population level by vaccinating all stray and pet dogs.

Pre-Exposure Prophylaxis

It is recommended for high risk groups like veterinarians, laboratory personnel working with rabies virus, medical and paramedical personnel treating rabies patients, dog catchers, forest staff and zoo keepers.

Post-Exposure Prophylaxis

Depending on the severity of the exposure and categories of exposure, the recommended treatment for each is shown in **Table 3**. All exposures in the wild are category III exposures. Rodents are not reservoirs of rabies virus. Small rodents (e.g. squirrels, chipmunks, rats, mice, hamsters, guinea pigs, and gerbils) and lagomorphs (including rabbits and hares) are rarely infected with rabies and have not been known to transmit rabies to humans.

Following exposure, wound care consists of washing the wound with soap and water while avoiding touching the wound with bare hands. Post-exposure immunisation can be discontinued if the animal is healthy after 10 days.

Vaccines available in India include purified duck embryo, purified chick embryo, Vero cell (cell line from kidney epithelial cells of African Green monkey) derived and human diploid cell vaccine.

Rabies immunoglobulin, used to provide passive protection, is available as a human and an equine preparation. Anaphylactic shock may occur following the administration of equine preparations. Skin testing should be performed before giving

the injection by injecting 0.1 mL of equine rabies immunoglobulin, diluted 1:10 in saline, intradermally into the flexor surface of the forearm to raise a bleb of 3 mm diameter. An equal amount of saline is injected as control in the other forearm. After 15 minutes, an increase in diameter to >6 mm of wheal surrounded by flare is taken as a positive skin test.

Table 3: Categories of Exposure and Recommended Treatment for Rabies

Category I

Touching, feeding of animals or licks on intact skin

Recommendation: If history is reliable, no prophylaxis is indicated

Category II

Minor scratches or abrasions without bleeding or licks on broken skin and nibbling of uncovered skin

Recommendation: Wound management and use of vaccine

Category III

Single or multiple transdermal bites, scratches or contamination of mucous membrane with saliva (i.e. licks), exposure to bats

Recommendation: Wound management plus rabies immunoglobulin plus immunisation

Passive immunisation: It provides immediate protection to previously unvaccinated individuals. Human rabies immunoglobulin (HRIG) is used in a dose of 20 IU/kg (maximum 1,500 IU). If HRIG is not available, equine rabies immunoglobulin should be used in a dose of 40 IU/kg (maximum 3,000 IU). Rabies immunoglobulin should be infiltrated into and around the wounds; leftover immunoglobulin, if any, should be given intramuscularly at a site away from the site of vaccine administration. Passive immunisation is not indicated in individuals who have previously received the vaccine.

Table 4: Recommended Dosage Schedule for Rabies Vaccine

Situation	Dosing schedule
Pre-exposure prophylaxis	Days 0, 7, 28
Post-exposure prophylaxis (no prior immunisation) (Category II or III exposure)	Days 0, 3, 7, 14, 28 + RIG on day 0
*Post-exposure prophylaxis – New CDC guidelines**	*Days 0, 3, 7, 14 + RIG on day 0*
Re-exposure after a full course of immunisation	Days 0, 3
Re-exposure after incomplete course of immunisation	Treat as if previously not vaccinated

RIG = Rabies immunaglabulin; Dase = 10 IU/kg af human RIG ar 20 IU/kg af equine RIG infiltrated araund the waund. Leftaver RIG shauld be injected intramuscularly at a site away fram that af vaccine administratian.

**CDC. Use of a reduced (4-Dose) vaccine schedule for past-expasure praphylaxis ta prevent human rabies.*

Recammendatians af the Advisary Cammittee an Immunisatian Practices. MMWR Morb Mortal Wkly Rep 2010; 59(RR-2):1-9.

The vaccine is administered intramuscularly in the deltoid or in the anterolateral thigh. It should not be given in the gluteal region since the high fat content of this site retards vaccine uptake. Recommended dosage schedules are shown in **Table 4**. Bites sustained during sleep or those due to unidentified animals should presumptively be treated in India as if due to a possibly rabid animal. No consensus is available regarding the management of bites due to wild rodents and treatment needs to be individualised. Rabies vaccines and rabies immunoglobulin are safe during pregnancy, lactation and in immunocompromised states including human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS). Minor reactions at the local site of injection and rare cases of anaphylaxis have been reported. Immunospuppresive drugs should be avoided during the course of immunisation.

HEPATITIS B

Hepatitis B and its complications like hepatic failure, cirrhosis and hepatocellular carcinoma account for significant morbidity and mortality. Hepatitis B immunisation remains the most effective measure to prevent hepatitis B virus (HBV) infection.

Percutaneous or mucosal exposure can occur in injection-drug users; household contacts of persons with chronic HBV infection; health care workers; patients with chronic kidney or liver disease; HIV-positive patients; diseases where blood products or multiple blood transfusions are required, and patients undergoing major surgeries. Sexual exposure (homosexuals, promiscuous heterosexuals, commercial sex workers and sex partners of HBsAg-positive persons) may also be associated with transmission of the virus.

Immunisation is indicated for all unvaccinated adults at risk for HBV infection and all adults seeking protection from HBV infection, including post-exposure prophylaxis.

Hepatitis B vaccine, a recombinant DNA vaccine, is available as a single-antigen formulation and also in fixed combination with other vaccines. For immunocompetent adults, 20 µg of recombinant vaccine is administered at 0, 1, and 6 months as an intramuscular injection in the deltoid muscle using a 24 to 38 mm needle. Protective antibody levels, defined as anti-HBs antibody titers of 10 mIU/mL or higher, are seen in approximately 30% to 55% of healthy adults aged <40 years after the first dose, 75% after the second dose, and >90% after the third dose.

Prevaccination Screening

It is not cost-effective in India. It may be cost-effective in adult populations with a prevalence of HBV infection of >20%, such as household, sexual, and needle-sharing contacts of HBsAg-positive persons; HIV infected persons; injection drug users; men who have sex with men; patients with chronic liver disease (CLD) and end-stage renal disease (ESRD). Prescreening requires testing for HBsAg, anti-HBs and anti-HBc. If HBsAg is positive or Anti-HBs titres are more than 10 mIU/mL, immunisation is not required. In those in whom both anti-HBc and anti-HBs are negative, immunisation should be administered. If Anti-HBc alone is positive, a test dose of the vaccine should be given and anti-HBs titers repeated after a month. Immunisation is required only in those who have titers of less than 10 mIU/mL at one month.

If the *vaccine schedule is interrupted* after the first dose, the second dose should be administered as soon as possible, and the second and third doses should be separated by an interval of at least eight weeks. If only the third dose has been delayed, it should be administered as soon as possible.

Post-Exposure Screening

It is indicated in patients with ESRD, CLD, HIV infection, sex partners of HBsAg-positive persons, infants born to HBsAg-

positive women and certain health care workers at high risk exposure of to blood or body fluids.

Non-responders who are HBsAg and anti-HBc negative should receive a further full course of immunisation as fourth, fifth and sixth doses. Retesting should be done 1 to 2 months after the last dose. If there is no response, 40 µg of recombinant vaccine is administered at 0,1, and 6 months. For patients with chronic kidney disease (CKD) and other immunosuppressed patients, 40 µg of recombinant vaccine is administered at 0, 1, 2, and 6 months.

A *booster dose* should be administered when anti-HBs levels decline to less than 10 mIU/mL (<100 mIU/mL in patients on dialysis). For CKD patients, the need for booster doses should be assessed by annual anti-HBs antibody titre testing. Testing for antibody titers and administration of booster doses of HBV vaccine are generally not indicated in persons with a normal immune status. Other than local injection site reactions and rare cases of anaphylaxis, no serious adverse events have been reported. The vaccine is safe during pregnancy.

PNEUMOCOCCAL DISEASE

Pneumococcal polysaccharide vaccine (PPV) substantially reduces the risk of development of invasive pneumococcal disease but not all-cause mortality. Routine administration of the vaccine to all adults is not a cost-effective strategy. Immunisation is recommended in patients undergoing splenectomy (preferably at least two weeks prior to surgery) and one-time reimmunisation is indicated after five years in these patients. Many indications for which immunisation is recommended in developed countries, such as the healthy elderly and high-risk patients, are not considered indications for immunisation in India.

The PPV contains 25 µg each of purified capsular polysaccharide from 23 serotypes of *Streptococcus pneumoniae*. A single dose of 0.5 mL is administered by the intramuscular or subcutaneous route. This vaccine can be co-administered with live vaccines, such as the influenza vaccine. It is safe and adverse events, except local reactions are few. With the exception of the first trimester of pregnancy, there are no contraindications to vaccine use.

INFLUENZA

Seasonal influenza, an infection transmitted by respiratory droplets, causes significant illness especially in the elderly and the immunocompromised. Since treatment options are limited, immunisation is an attractive option. In 2009, the emergence of a new recombinant strain of the virus H1N1, lead to a pandemic affecting individuals on all continents. The response to this pandemic has been rapid and a vaccine is already in use.

An Indian Expert Group on Adult Immunisation found no evidence to recommend the use of seasonal influenza vaccine in adults. In Western countries, this vaccine is routinely recommended for the elderly, those with COPD and patients with chronic pulmonary, renal or cardiac disease.

Data are not available to guide the use of H1N1 influenza vaccine in India. This vaccine has routinely been administered in Western countries during the winter of 2009. Priority groups to whom vaccine should be given first are shown in **Table 5**.

Seasonal Influenza

Two types of vaccine are available: trivalent inactivated influenza vaccine (TIV) and live attenuated influenza vaccine (LAIV). The TIV is administered by an annual, single intramuscular dose of 0.5 ml. The LAIV is administered by the intranasal route and is approved for use in adults aged up to 50 years.

H1N1 Influenza 2009

Immunisation against seasonal influenza does not provide cross-protection against H1N1 influenza. Specific vaccines have been developed against the H1N1 strain. A single dose of the vaccine provides protection starting as early as three weeks. Vaccine efficacy ranges from 70% to 90%. Available vaccines include a killed inactivated vaccine and a live-attenuated intranasal vaccine (LAIV). The former is given as a single dose of 0.5 ml [15 µg hemagglutinin of A/California/7/2009 (H1N1) pdm] intramuscularly in the deltoid. The live attenuated vaccine is given in a single dose of 0.2 mL divided equally between each nostril.

Inactivated vaccine against the 2009 H1N1 flu virus can be given at the same visit as any other vaccine, including PPV. The LAIV (nasal spray vaccine) against the 2009 H1N1 virus can be administered at the same visit as any other live or inactivated vaccine except seasonal live-attenuated influenza vaccine because of concerns about competition between the two vaccine viruses.

Adverse effects are similar for immunisation against seasonal influenza and H1N1 influenza. Inactivated vaccines, administered by injection, commonly cause local reactions, such as soreness, swelling and redness at the injection site. Inactivated vaccines should not be given to individuals with egg protein allergy. Live vaccines are given via a nasal spray, and can commonly cause runny nose, nasal congestion, cough, and sore throat, low grade fever, irritability and headache. H1N1 influenza vaccine can be safely given during pregnancy. LAIV should not be administered to persons with asthma because of the potential for increased risk of wheezing post-vaccination, unless the potential benefits outweigh the potential risks.

TYPHOID

Immunisation may help reduce disease burden in areas with a high incidence of this disease. The vaccine should be given to all adolescents. Administration to all adults is not recommended. However, during an outbreak, the entire community may be vaccinated.

Two vaccines, injectable Vi polysaccharide vaccine and live oral Ty21a vaccine, are recommended for use. Live oral Ty21a vaccine is an orally administered, live-attenuated Ty2 strain of *Salmonella typhi* in which multiple genes have been mutated chemically. The lyophillised vaccine is available in two formulations: a liquid suspension (in sachets) or as enteric coated capsules. Four doses are given on alternate days. This series has to be repeated once in three years as a booster dose. The capsule formulation should be taken orally with plain, cold or lukewarm water. The sachet should be given with 100 mL of safe water with buffer to protect the B-subunit against gastric acidity. Following the administration of the vaccine, food should be taken only after one hour. Proguanil and anti-bacterial drugs should not to be given for 3 to 7 days before and after the course of vaccine.

Table 5: Summary of Immunisation Schedule for Adults

Vaccine	Target Population	Dose	Dosage Schedule	Protection Rate	Remarks
Hepatitis B (Recombinant DNA vaccine)	All adults	20 µg IM in deltoid muscle *(do not inject into buttocks)* 40 µg IM in haemodialysis and other immuno-compromised patients	0, 1, 6 months	>90% after the third dose	Testing for protective concentration of anti-HBs antibody (>10 mIU/mL) should be performed 1 to 2 months after the last dose of the vaccine series. Persons with >10 mIU/mL are considered to be immune. Immunocompetent persons have long-term protection and do not require further testing, however, immunocompromised persons might need annual testing to assess anti-HBs antibody levels. The level should be >100 mIU/mL in CKD patients
Pneumococcal Polysaccharide vaccine (23 valent polysaccharide vaccine)	Two weeks prior to elective splenectomy. One time revaccination with PPV after 5 years is recommended in patients with functional or anatomic asplenia	0.5 mL IM or s.c.	Single dose	0% to 66%	The scientific evidence for the efficacy of PPV has been a very controversial issue. Evidence for the efficacy of PPV in high-risk groups is lacking. In resource-limited settings, routine PPV vaccination is not recommended for healthy elderly (>65 years) and high-risk patients, such as those suffering from chronic organ failure, diabetes, nephritic syndrome, or HIV infection
Seasonal influenza [Trivalent inactivated vaccine (TIV) and live attenuated influenza vaccine (LAIV)]	Elderly, COPD, chronic pulmonary, renal or cardiac disease	TIV: 0.5 mL IM LAIV: 0.2 mL Intranasal	Annual, single dose	70%	Evidence insufficient for use in India
H1N1 Influenza [killed inactivated vaccine; live attenuated intranasal vaccine (LAIV)]	Pregnant women Health care workers Age 6 months to 24 years Age 25 to 64 years with high-risk medical conditions	Killed inactivated vaccine: 0.5 mL IM Live vaccine: 0.2 mL (half in each nostril)	Single dose	Above 90%	Do not give killed vaccine to those with egg allergy. Avoid LAIV in asthma
Typhoid (Injectable Vi polysaccharide vaccine; Live oral Ty21a vaccine)	All adolescents	Vi polysaccharide: 0.5 mL IM or s.c. Live Ty21a: 1 capsule, orally four doses on alternate days	Vi polysaccharide: Booster every 3 years. Ty21a: Repeat series once in 3 years	51% to 55%	Entire community during an outbreak
Cholera [Oral: Shanchol Lipopoly-saccharide of formalin killed *V. cholera* (5 strains)]	Adults in endemic areas and during potential/actual outbreaks	300 to 600 IU of different strains	Two doses 1 to 6 weeks apart. Booster every second year	67%	Protective efficacy of 67% over two years in all age groups
Meningococcal (Polysaccharide – Bi- and Quadri-valent Conjugate)	Travellers, pilgrims and people attending fairs and festivals. Health care personnel. Haj pilgrims administered a single dose of quadrivalent vaccine	Polysaccharide: 0.5 mL s.c.	Single dose	85% to 95%	Does not induce herd immunity; no effect on nasopharyngeal carriage. Safe in pregnancy and in HIV + patients

Contd...

Contd...

Vaccine	Target Population	Dose	Dosage Schedule	Protection Rate	Remarks
Japanese encephalitis (live-attenuated SA 14-14-2 vaccine)	1 to 15 years	0.5 mL s.c.	Single dose	90% to 100%	Recommended in adolescents
Yellow fever (live, attenuated virus preparation made from the 17D yellow fever virus strain)	Travellers visiting Africa and South America	0.5 mL s.c.	Single dose	95%	Protective antibodies develop 10 days following immunisation
Human papilloma virus (Bivalent HPV 16/18 vaccine; Quadrivalent HPV 6/11/16/18 vaccine)	Girls 10 to 12 years Men 9 to 26 years to prevent genital warts	0.5 mL IM	Bivalent: 0, 1, 6 months Quadrivalent: 0, 2, 6 months	97% to 100%	Immunise before sexual activity commences
Herpes zoster (lyophilised preparation of the Oka strain of live-attenuated varicella zoster virus (VZV))	Adults >60 years Chronic medical conditions with an increased risk of herpes zoster	0.65 mL s.c.	Single dose	51%	Protect from light before reconstitution Use immediately to minimise loss of potency

Nate: Details af immunisatian against tetanus and rabies are pravided in Tables 1 ta 4.

s.c. = Subcutaneous; IM = Intramuscular.

Live attenuated influenza vaccine, human papilloma virus vaccine and oral Ty21a typhoid vaccines varicella and herpes zoster vaccines are contraindicated during pregnancy. The safety of Japanese encephalitis vaccine and of yellow fever vaccine has not been established in pregnancy and their use should be avoided. All other vaccines may be safely administered to pregnant women.

Booster doses are required only for hepatitis B (those with low anti-HBs titres), cholera (every 2nd year) and typhoid (every 3 years) immunisation.

The Vi polysaccharide vaccine is a subunit vaccine composed of purified Vi capsular polysaccharide from the Ty2 *S. typhi* strain and elicits a T-cell independent IgG response that is not boosted by additional doses. The target value for each single dose is about 25 µg of the antigen.The Vi vaccine is given as a single subcutaneous or intramuscular dose of 0.5 mL. A booster is recommended every three years.

Both live oral Ty21a and Vi polysaccharide vaccines have an efficacy of 51% to 55% at three years and may be co-administered with other killed/live vaccines. Abdominal discomfort, nausea, vomiting, fever, headache and rash or urticaria have been reported in some patients after oral Ty21a vaccine administration. Vi polysaccharide immunisation can result in fever, headache and erythema or induration. The Ty21A vaccine should not be used during pregnancy. In HIV seropositive individuals with a CD4+ T-lymphocyte count >200/mm^3, both Ty21a and Vi vaccines can be administered. However, in HIV-seropositive individuals with a CD4+ T-lymphocyte count <200/mm^3, Vi vaccine should be used.

CHOLERA

Immunisation, a part of the strategy for reducing cholera related morbidity, is primarily targeted at children. However, in endemic areas and during potential/actual outbreaks, adults may also be given the vaccine.

Two types of vaccines are used: (1) injectable killed whole cell vaccine; and (2) oral cholera vaccine. The injectable killed whole cell vaccine provides protection for a duration of only 3 months. Two doses of the vaccine are administered one week to one month apart. The use of this vaccine is no longer recommended.

Among the oral cholera vaccines, Dukoral (WC/rBS) consists of 1 mg of recombinant cholera toxin B subunit plus 2.5 x 10^{10} of four *V. cholerae* O1 strains. In adults, Dukoral (WC/rBS) is administered as two separate doses, 1 to 6 weeks apart. It confers 85% to 90% protection for six months. The protection remains at about 60% after two years.

A variant of the WC/rBS oral cholera vaccine that does not contain the cholera toxin recombinant B-subunit was available as Vabiotech vaccine (made in Vietnam). It was administered in two separate doses given one week apart.

The manufacture of this vaccine has been taken over by Shantha Biotechnics, with the trade name Shanchol. This preparation was evaluated in Kolkata in a randomised controlled trial including over one lakh participants. It was found to have a protective efficacy of 67% over two years in all age groups with few adverse effects. Based on these results, the WHO, in a position statement published in March 2010 recommends the use of the oral vaccine with initial immunisation (two doses) followed by a booster dose every second year. With the oral vaccine, diarrhoea, fever, vomiting and abdominal pain have been reported to occur in some patients.

MENINGOCOCCAL DISEASE

The case fatality rate for meningococcal infections is 10% to 15%. Immunisation plays an important role in preventing these infections. Outbreaks of meningococcal disease occur in crowded living conditions, such as in dormitories; in military recruits and in jail inmates. Immunisation should be restricted to high risk populations or for travellers, pilgrims and people attending fairs and festivals. Health care personnel handling outbreaks and laboratory workers need to be immunised.

Two types of vaccines are available: (i) polysaccharide vaccines; and (ii) conjugate vaccines. Polysaccharide vaccines are available as bivalent (A+C) or quadrivalent (A, C, Y, W135) preparations. The vaccine is available as a lyophilized vaccine containing 50 µg of polysaccharide per dose. After reconstitution with sterile saline solution, the vaccine has to be used on the same day, preferably within 8 to 12 hours. A single dose of 0.5 mL of the reconstituted vaccine is administered subcutaneously in the deltoid region. The vaccine does not induce herd immunity and has no effect on nasopharyngeal carriage.

For Haj pilgrims, a single dose of quadrivalent vaccine is given in accordance with the requirements of the Government of Saudi Arabia. Other than minor injection site reactions, adverse effects are rare. The vaccine can be safely given to pregnant women and HIV positive persons.

JAPANESE ENCEPHALITIS

Japanese encephalitis (JE), caused by a mosquito-borne flavivirus, is the most common vaccine-preventable cause of encephalitis in India. In endemic countries, JE is primarily a disease of children. No effective treatment is available for JE. The JE vaccine is primarily useful in the age group of 1 to 15 years. The vaccine is not recommended for routine use in adults. Vaccines used for immunisation are (i) mouse brain-derived inactivated vaccine that uses the Nakayama strain (e.g. BIKEN/ JE-VAX®) and (ii) PHK cell-cultured, live-attenuated vaccine (e.g. SA 14-14-2 vaccine). The SA 14-14-2 vaccine is administered subcutaneously as a single 0.5 mL dose in India. The vaccine is safe and few adverse effects have been noted.

YELLOW FEVER

This is a mosquito-borne viral disease that occurs only in some parts of Africa and South America. Travellers planning to visit such areas should be vaccinated. Yellow fever vaccine is a live-attenuated virus preparation made from the 17D yellow fever virus strain. A single subcutaneous injection of 0.5 mL of reconstituted vaccine is used. Mild headache, myalgia, low-grade fever, and other minor symptoms may occur after immunisation. Rare cases of post-vaccinal encephalitis have also been reported. Protective antibodies develop 10 days following immunisation.

HUMAN PAPILLOMA VIRUS

Carcinoma of the cervix is the commonest malignancy in Indian women. Infection with high risk strains of the human papilloma virus, such as HPV-16 and HPV-18 has been implicated in the pathogenesis of cervical cancer. Immunisation against these viral strains has been shown to reduce the incidence of carcinoma cervix. Immunisations should ideally be done before sexual activity commences. The Indian Academy of Pediatrics has included the HPV vaccine as a Category 2 vaccine and recommended its use in girls aged 10 to 12 years.

Two vaccines are currently licensed: A bivalent HPV 16/18 vaccine containing 20 µg each of L1 HPV16 and L1 HPV18 (GlaxoSmithKline - Cervarix™) and a quadrivalent HPV 6/11/16/ 18 vaccine containing L1 HPV6 and L1 HPV 18 (20 µg each) and L1 HPV 11 and L1 HPV16 (40 µg each) (Merck Sharp and Dohme – Gardasil™). Cervarix is given 0.5 mL intramuscular in the deltoid at 0, 1, and 6 months. Gardasil is given 0.5 mL intramuscular in the deltoid at 0, 2, and 6 months.

Vaccine efficacy is approximately 97% to 100% and protection lasts for at least five years. Booster doses are not recommended. Interruptions in the vaccine schedule, longer than one year, necessitate re-starting the schedule. The quadrivalent vaccine may be given to males aged 9 through 26 years to reduce their likelihood of acquiring genital warts. It would be most effective when administered before exposure to HPV through sexual contact.

Local injection site reactions and headache are common. The vaccine is contraindicated during pregnancy and in patients with a history of hypersensitivity to any of the vaccine components. It can safely be given during lactation and to immunodeficient individuals.

HERPES ZOSTER

The vaccine is recommended for immunocompetent individuals aged 60 years or older. Herpes zoster vaccine has been found to decrease the incidence of herpes zoster by 51% and of post-herpetic neuralgia by 67%. The vaccine was licenced by the US FDA in May 2006. Unlike other adult vaccines, this vaccine requires freezer storage and is the most expensive vaccine routinely recommended for older adults.

CHICKEN POX

Vaccination against varicella is not recommended in developing countries.

The recommended immunisation schedule for adults (except for tetanus and rabies) is summarised in **Table 5**.

28.8 Perioperative Management

Prabha Adhikari

'*Primum non nocere*' (first do no harm) is the motto of medicine and the same holds good for perioperative medicine which is an art, based on weighing risks against benefits. There are certain questions faced by the surgeon and the patient who has to undergo surgery. Preoperative evaluation should try to answer the following questions:

1. What are the risks of surgery and general anaesthesia?
2. What are the predictors of those risks?
3. Can they be reduced by pre-operative measures?
4. What are the anticipated intraoperative and post-operative complications?
5. What are the measures in the event of these complications?

Perioperative management encompasses pre-operative evaluation, recommendations for prevention of intraoperative and post-operative complications, and management of post-operative complications.

PRE-OPERATIVE EVALUATION

First, classify your patient under ASA Scale, which will give a general idea to the surgeon and anaesthetist regarding risk of mortality and then classify the patient as high risk cardiac case, high risk pulmonary case, other high risk case or healthy individual (**Table 1**).

Table 1: American Society of Anaesthesiologist Physical Scale and Mortality Prediction in the Perioperative Period (For Emergency Surgery Mortality Doubles)

Class	Description	Mortality Rate
I	Healthy individual	0.1%
II	Mild systemic disease	0.2%
III	Severe systemic disease	1.8%
IV	Incapacitating systemic disease, which is a constant threat to life	7.8%
V	Moribund patient, who is likely to die with or without surgery	9.4%

ASSESSMENT OF CARDIAC RISK

Modified Goldman's Risk Index for non-cardiac surgery (**Table 2**) assesses the risk involved in cardiac patients for non-cardiac surgery. Recent myocardial infarction (MI), grade III or IV angina and active congestive heart failure, are the most important risk factors for cardiovascular mortality and morbidity.

Complications that occur in these high risk patients are acute myocardial infarction, cardiogenic pulmonary oedema, ventricular arrhythmia or cardiac death. Based on the scores, risk class is derived as shown in **Table 3**.

Other risk factors for cardiac disease which are not included in the Goldman's risk index include diabetes mellitus, poorly controlled hypertension, and poor exercise tolerance. Inability to exercise for at least two minutes on a bicycle at a rate of 50 revolutions per minute to a heart rate >99/min is a strong predictor of perioperative complications. Hence, all these points need to be considered, in addition to Goldman's risk index, in predicting cardiovascular morbidity/mortality.

Table 2: Modified Goldman's Risk Index for Non-cardiac Surgery (Detsky's modification) (Score >20 High Risk)

Risk Factors	Risk Score
Coronary artery disease	
MI within 6 months	10
MI more than 6 months old	5
Angina class III	10
Angina class IV	20
Unstable angina within 3 months	10
Alveolar pulmonary oedema or signs of CCF	
Within 1 week	10
Ever	5
Critical aortic stenosis	20
Arrhythmias	
Rhythm other than sinus or sinus plus Atrial premature beats >5	5
Greater than 5 ventricular premature beats	5
Poor general medical status	5
PO_2 <60 mm Hg, PCO_2 >50 mm Hg or Potassium <3 mEq/l, Bicarbonate <20 mEq/l or BUN >50 mg/dl, creatinine >3 mg/dl or Abnormal SGOT or signs of chronic liver diseases or Bedridden state due to non-cardiac causes	
Age >70 years	5
Emergency surgery	10

Table 3: Risk Class from the Goldman's Risk Index

Class	Scores	Mortality Rate
Class I	0 to 5	6%
Class II	6 to 12	7%
Class III	13 to 25	20%
Class IV	>26	100%

In 1999, Lee *et al.* revised Goldman's criteria for cardiac risk index and developed six independent predictors/variables which correlated with post-operative cardiac complications. Patients with more than 2 variables have a postoperative cardiac complication rate of ~10% and are considered to be high risk (**Table 4**).

Table 4: Revised Goldman's Criteria for Cardiac Risk Index

LEE Variables

1. High risk type of surgery
2. Ischaemic heart disease (includes any of the following: history of myocardial infarction, history of a positive exercise test, current complaint of chest pain that is considered to be secondary to myocardial ischaemia, use of nitrate therapy, or electrocardiography with pathologic Q waves)
3. Congestive heart failure
4. History of cerebrovascular disease
5. Pre-operative treatment with insulin
6. Pre-operative serum creatinine >2 mg/dL

LEE Criteria – Revised Cardiac Risk Index

Number of variables	Risk of major post-operative cardiac complication
0	0.4%
1	0.9%
2	7%
3	11%

Major risk factors: control and stabilise before surgery

- Unstable or severe angina
- Recent MI
- Decompensated HF
- Significant arrhythmias
- Severe valvular disease

Intermediate risk factors

- History of ischaemic heart disease
- History of compensated or previous HF
- History of cerebrovascular disease
- Diabetes mellitus
- Renal insufficiency

Minor risk factors

- Advanced age (greater than 70 years)
- Abnormal ECG (LV hypertrophy, left bundle branch block, ST-T abnormalities)
- Rhythm other than sinus
- Uncontrolled systemic hypertension

Elective Non-Cardiac Surgery and Anti-Platelet Therapy in Patients with Previous PCI

Anticoagulants like subcutaneous fractionated or unfractionated heparin do not substitute the antiplatelet protection of thienopyridine and/or aspirin therapy in patients with bare-metal or drug-eluting stents undergoing non-cardiac surgery.

Delay elective surgery until more than 1 year post drug-eluting stent placement (DES). In case it needs to be done, risk assessment with cardiologist for discontinuation of clopidogrel or ticlopidine for 5 days, or prasugrel for 7 days perioperatively is necessary. Proceed to surgery with aspirin or, if indicated, with dual antiplatelet therapy. If dual therapy or aspirin was discontinued give a single aspirin 325 mg dose immediately preoperative period and post-operatively continue aspirin and resume dual therapy as soon as feasible, preferably by 2nd/3rd day.

In patients who underwent balloon angioplasty only, delay surgery until more than 14 days post-balloon angioplasty. At more than 14 days proceed to surgery with aspirin. If aspirin therapy was discontinued, give a single aspirin 325 mg dose immediately pre-operatively and continue aspirin, postoperatively.

In patients with Bare metal stents, delay surgery until more than 45 days (preferred; minimum 30 days) post bare-metal stent placement. However, if surgery needs to be done whether before or after 45 days risk assessment should be done with cardiologist for discontinuation of clopidogrel or ticlopidine for 5 days, or prasugrel for 7 days pre-operatively. Proceed to surgery with aspirin or, if indicated, with dual antiplatelet therapy. If dual therapy was discontinued give a single aspirin 325 mg dose immediately pre-operatively. Post-operatively continue aspirin and resume dual therapy as soon as feasible, preferably by 2nd/3rd day.

Investigations in High Risk Cardiac Cases

In high risk cases, ECG, Echocardiography for detection of LV dysfunction, stress testing, intraoperative cardiac monitoring for arrhythmias, ST-T changes and invasive haemodynamic monitoring, such as arterial pressure, central venous pressure, pulmonary wedge pressure for high risk cases scheduled for high risk surgeries.

RISK OF PULMONARY COMPLICATIONS (PULMONARY RISK CASE)

There is no risk score in pulmonology to predict complications. However, there are general risk factors which predict post-operative pulmonary complications (**Table 5**).

Table 5: Pulmonary Risk Factors

Age >70 years
Obesity
Smoking history
Poor nutrition
Antecedent respiratory infection
Intrathoracic or upper abdominal surgery
Prolonged anaesthesia time
Poor general medical status
Pre-existing pulmonary disease: Obstructive lung disease is a greater risk than restrictive lung disease

Anticipated Complications

Minor complications

These include bronchitis, tracheobronchitis, and exacerbation of COPD.

Major complications

These include atelectasis, pneumonia, respiratory failure, need for prolonged ventilatory therapy, and pulmonary embolism.

Pre-operative Evaluation

It includes detailed history, respiratory rate, presence of cyanosis, clubbing, oedema, presence of emphysema, rhonchi, increased forced expiratory time, absent or decreased tidal percussion (indicative of COPD), Scadding sign (in-drawing of suprasternal notch with each inspiration) and fine crepitations indicative of

restrictive lung disease. Obstructive lung disease has more deleterious effects on a surgical patient.

Investigations for High Risk Care

Chest radiograph, spirometry, FEV1/FVC and FEV1 reliably predict risk of complications. Peak expiratory flow rate (PEFR) measurements done serially may predict post-operative complications. Persistent hypercapnia on arterial blood gas analysis in a patient with COPD is associated with pulmonary morbidity. Sputum microbiological studies and ECG are needed in some patients.

Measures to Reduce Complications

Several measures help in reducing complication rates (**Table 6**). In our own experience, daily postoperative PEFR measurements is highly recommended for prediction of complications. Artificial ventilatory facilities, throat suction, measures for adequate oxygen delivery, facilities for pulse oximetry, and arterial blood gases should be available.

Table 6: Measures to Reduce Pulmonary Complications Post-Operatively

Pre-operative measures
Smoking cessation (minimum of 8 weeks prior to surgery)
Optimise airway function – bronchodilators, corticosteroids, control of infection by antibiotics, chest physiotherapy
Weight reduction, if obese
Education on post-operative deep breathing exercise, importance of coughing, or use of incentive spirometry, wherever available
Post-operative measures
Early mobilisation and ambulation
Prophylactic lung expansion manoeuvres: deep breathe hourly or incentive spirometry
Adequate analgesia
Prophylaxis for deep vein thrombosis

Surgery in a Patient with Diabetes Mellitus

Half of all diabetics undergo surgery at sometime in their lives. Diabetic surgical patients have special problems due to metabolic, vascular and neurological impairments. They are also prone for infection and delayed wound healing.

Metabolic problem

Both ketosis, the effect of under treatment and hypoglycaemia, the effect of over treatment can adversely affect patients during surgery.

Vascular disease

CAD may induce acute myocardial infarction, cerebrovascular disease may induce stroke due to haemodynamic instability or hypoxia during surgery. Nephropathy may lead to acute kidney injury and other metabolic complications.

Autonomic neuropathy

It may induce haemodynamic instability and cardiac arrhythmias. Anxiety, anaesthesia and surgery may create stress and release anti-insulin hormones and consequently hyperglycaemia leading to infections and delayed wound healing. Insulin dependent diabetics have a higher risk of deep vein thrombosis.

Pre-Operative Evaluation

Assess glycaemic status: Fasting and post-prandial blood sugar and HbA1c. If the HbA1c is >9%, insulin should be started. If above 12%, consideration should be given to improving control before elective surgery is undertaken.

Assess cardiac risk by detailed history and cardiac risk score.

Evidence of peripheral vascular disease may indirectly suggest co-existing coronary artery disease.

Look for carotid bruits.

Assess for cardiac autonomic neuropathy by electro-cardiogram for CAD and heart rate variability (HRV) after deep breathing. HRV of <5 beats/min signifies serious cardiac autonomic neuropathy and prone for arrhythmias.

Assess renal risk by blood urea, creatinine, electrolytes, urinary proteinuria, and microalbuminuria.

Detect hypertension or orthostatic hypotension.

Pre-Operative Measures

Optimise treatment of diabetes and control of hypertension.

Aims of the treatment

- Avoid ketosis or hypoglycaemia. Hypoglycaemia may go unrecognised in a patient under anaesthesia and may lead to permanent damage. The ideal blood glucose level is 150 to 200 mg/dl. Tight control of 80 to 150 mg/dl is recommended for those with shorter duration of diabetes.
- Adequate insulin administration.
- Anticipate cardiac or renal problems.

Control of blood glucose during surgery

All patients must have their fasting capillary blood glucose checked on the day of surgery.

Diet controlled diabetics and well controlled diabetics on metformin or short acting sulfonylureas—no food, no glucose, and no insulin.

Those on long-acting sulphonylureas—these drugs are stopped one day prior to surgery

They need intravenous glucose on the day of surgery. All major surgeries and insulin treated patients are managed with GIK infusion as follows:

Glucose-insulin-potassium regimen: Skip morning dose of insulin. 5 to 10 units of insulin + 10% dextrose + 10 MEq potassium – at the rate of 100 ml/hr starting half an hour before surgery (if diabetes poorly controlled, 10 to 20 IU of insulin and 5% dextrose can be used). Use of 5% dextrose with 10 IU of insulin and 10 MEq of potassium has been used with excellent results.

Post-Operative Management

Patient needs continued glucose infusions with insulin till oral feeds are started. Once oral feeds are started, either rapid acting insulins may be used or alternatively only basal insulin may be given if patients are tube fed or on liquids only. Once they are taking regular meals, pre-operative insulin regimen may be administered.

Other post-operative measures

Frequent capillary blood glucose monitoring, repeat ECG, early ambulation and prophylaxis for deep vein thrombosis for high risk cases and incentive spirometry.

SURGERY IN A HYPERTENSIVE PATIENT

Hypertension, per se, is not a risk factor for surgery. However, a poorly controlled hypertensive with or without CAD can develop haemodynamic instability during surgery, which can be deleterious to the heart. Hypertension should be well controlled prior to surgery. A blood pressure of >180/110 mm Hg warrants to postpone the surgery. However, Stage I and Stage II hypertension with no additional cardiovascular disease risk, can proceed for surgery. Patients on ACE inhibitors or ARB may develop post-operative hypotension if volume depleted.

Recommendations

The patient should continue his antihypertensive drug even on the day of surgery with a sip of water and continue the same post-operatively after resumption of oral feeds. Only diuretics need to be stopped 24 to 48 hours prior to surgery. Patients on diuretics need a serum potassium check before surgery. Acute uncontrolled perioperative hypertension can be controlled with sodium nitroprusside, nitroglycerine, hydralazine, diazoxide or labetalol injection. Beta blockers appear to be particularly attractive agents for the treatment of pre-operative high blood pressure. Beta-blockers effectively modulate blood pressure fluctuations; reduce perioperative coronary ischaemic episodes, post-operative atrial fibrillation, and other cardiovascular complications. Drugs like sublingual nifedipine and enalapril cause unpredictable responses and may cause significant hypotension, which can be deleterious in patients with coronary artery disease and cerebrovascular disease.

HOW MUCH SHOULD YOU INVESTIGATE A HEALTHY INDIVIDUAL?

Who is a healthy individual? One who has no disease, does not smoke or consume alcohol, exercises regularly and has normal weight and nutrition is considered normal. If age is less than 40 years the investigations needed are haemoglobin and blood glucose. Haemoglobin, blood glucose, blood urea, and ECG are needed if age is between 40 and 50 years. The serum creatinine and chest radiograph are additional investigations to the previously mentioned tests in patients more than 60 years of age.

However, the situation in India may be totally different. Routine chest radiograph may uncover common diseases like tuberculosis. Eosinophil count is also important as tropical pulmonary eosinophilia, which is common in India, may predispose to bronchospasm during intubation. Elective surgery needs postponement in the event of a recent respiratory infection.

28.9 Law and Medicine

NK Grover

INTRODUCTION

The practice of Medicine involves not only scientific and technical knowledge, but also social, ethical and moral issues. The chosen person for delivery of health care—'the doctor' is perceived by society that he should be able to deliver a comprehensive range of healthcare activities, social work responsibilities and they would seek a 'Friend, Philosopher and Guide' in the doctor. The concept of health care has evolved to mean a comprehensive scheme, which promotes good health, prevents ill health, cures the sick and rehabilitates the disadvantages. This is a scheme which involves interaction amongst economic upliftment, public health, health education, targeted prevention and cure. Attempts to match the range and extent of health care to available resources constitute a yet unresolved ethical dilemma. The phenomenal advances in medical practice in recent times have elevated medical practise from its empirical avenues to a precision technology which has increased the cost very significantly. Failure to appreciate this qualitative change has led to the ethical dilemmas in doctors and the society in modern times.

There has been a significant change in the relationship between the patients and the physicians, from that of the 'Prime Healer Equivalent to God' to a mere 'Service Provider' in the present era. But the practice of medicine is guided by the principle '*Primun non nocere*' at least do no harm to the patient.

DOCTOR-PATIENT RELATIONSHIP

Doctors have always enjoyed respect much more than any other professional—a friend, philosopher, guide and even revered as 'Next only to God' because they have served to mitigate illness and promote health. The cornerstone of the doctor-patient relationship has been confidence, faith and trust which have gradually been eroded. The social position of doctor has changed to that of a service provider with obligation to inform and perform 'consented treatment'. This has happened due to many reasons like high tech, high cost medicine, rise in consumerism, increasing expectation of society and western influence where 'liability litigation' is order of the day.

The doctor-patient relationship has many moral, ethical and legal aspects while the relation has conventionally been fiduciary or trustee in nature. In today's era it has taken the shape of legal contract with many obligations. British Medical Association recommends healthy relationship between the two based on the concept of 'partnership and collaborative efforts' arrived by frank conversation, communication, consideration and consent. Such process allows patient to choose his preference and line of treatment with the guidance of physician leading to informed consent and shift of responsibility of outcome of disease and treatment of patient to some extent onto the patient in addition to treating doctor.

CONSENT

This is the crux and pivot which allows a doctor to manage illness in an appropriate manner. The consent is implied in outdoor consultation, for indoor treatment for any intervention or operation, it has to be taken in writing. It is an ethical and legal requirement and an essential obligation on the part of treating doctors, not obtaining a valid consent amounts to breach of duty. It should be as informed as possible, in the language patient understands and always properly documented. To give valid consent, a patient should be in sound state of mind, above the age of 18 years and put his signatures/thumb impression duly witnessed. Further consent today is the key to 'defence of doctor'. Special situations like serious patients require high risk or special or explicit consent. However, in emergency and life-threatening situations, the treatment cannot be withheld for want of consent. Special situations like unknown, unconscious patient or patient with insane mind require special avenues to tide over the issue of informed consent. In cases of infants and children consent may be given by the parent or guardian.

PATIENT'S CHARTER

Since enactment of Consumer Protection Act (1986) and its Amendment in 1993, the Central Consumer Protection Council (CCPC) in 1994, developed a 'Health and Patients Charter' which was notified by Government of India in February 1996. Some of its important features are:

1. Right to Healthcare and Humane Treatment
2. Right to Choice of Care
3. Right to Acceptable Safety
4. Right to Adequate Information
5. Right to Consent and Refusal
6. Right to Confidentiality
7. Right to Redressal of Grievances
8. Right to Health Education
9. Right to Participation and Representation
10. Right to Healthy Environment

The practitioners of medicine and institutions providing health care are obliged to respect patient's rights and privileges. Hospitals have similarly been made responsible with extra obligations like 'Right of Access' to all health facilities without any discrimination of sex, religion, caste or economic status. Emergency care, proper record keeping, patient safety protocol, standard of care, proper disposal of medical waste, etc. have specific guidelines and laws. Their preservation/destruction/certification and the medico-legal aspects require full understanding of responsibility by medical professionals. Hence doctors should carefully follow the stipulated rules to avoid any litigation in future.

MEDICAL ETHICS

Medical Council of India (MCI), a statutory body, was established in 1934 and re-enacted as MCI Act (1956) by the Parliament, Government of India. It is vested with powers to regulate and maintain standard of medical education, permissible standard of medical ethics and provision of penalties in the event of any violation of Code. Code of Medical Ethics was revised in 1970 and amended in December 2009 where it has enunciated doctor-pharmaceutical industry relationship in addition to existing ethical norms. Each doctor has to abide by this. MCI was superseded by the Board of Governors vide Indian Medical Council Amendment Ordinance 2010 vide Government of India Gazette Notification No. 2 of 2010 dated 15th May, 2010 to improve its functioning and tide over some of the alleged irregularities like nepotism, favouritism and financial irregularities.

MEDICAL NEGLIGENCE

'Negligence has been defined as omission to do something which a reasonable man guided by ordinary considerations would do or doing something which a reasonable and prudent man would not do' (Black's Law Dictionary). The word 'Negligence' under Legal Glossary (Govt. of India) means want of attention to what ought to be done or looked after, lack of proper care in doing something which a reasonable professional guided by considerations which ordinarily regulate the conduct of human affairs would do or not doing something which a prudent and reasonable man would not do. The British and Indian courts have repeatedly upheld this principle that conditions must be fulfilled to prove and have been enunciated by established latest judgments of Supreme Court of India.

The medical negligence arises only when you owe a duty. There is dereliction (breach) of that duty and damage (harm, complication or death) occurs which is 'directly attributable' to treatment given to the patient and not a mischance or complication which is well documented.

Types of Medical Negligence

Negligence has many manifestations, e.g. it may be active, passive, comparative, collateral, concurrent, continued, contributory, hazardous, gross, wilful, reckless and even criminal depending on the circumstances. Ordinarily, medical negligence is tried under Civil Laws, Laws of Contract, Tort or Consumer Protection Act, but in India it has criminal liability also.

Civil Laws Governing Medical Negligence and Laws of Contracts

When a doctor accepts or undertakes to treat a patient, in legal sense he is entering into a contract with the patient to render services adequately but not entering into any contract for curing the patient. He undertakes to use best of his skills and knowledge at all steps in diagnosis, treatment, administration of medicines, surgery and postoperative care, etc. This obligation is further augmented by law, commonly known as 'Law of Torts'. In Law of Torts, 'Tort' can be defined as 'Breach of Legal Duty' which is independent of contract and this breach entails damages. For medical professionals domain of 'Specific Tort' covers professional negligence. The patient can file a suit for damages/compensation by taking recourse to law of contract as well as Torts in Civil Courts.

Consumer Protection Act

To overcome the issue of cost and time taken by Civil Courts to settle the medical liability cases, Government of India promulgated a simple legal remedy 'Consumer Protection Act (1986)'. This Act provides for settlements of medical negligence suits and award compensation by Three Tier Redressal Mechanism, i.e. Forum at District level, State level, National Consumer Redressal Commission. Finally, Appellate Tribunal can also entertain cases directly where the financial stakes are high. After the National Commission one can only appeal to the Supreme Court.

Criminal Medical Negligence

There is very thin line of margin which can bring medical negligence within the ambit of criminality and attach liability under penal laws. To be so, negligence must be grave, gross, intended or wilful and with total disregard to the life of patient and doctor should have acted in haste without due care or without a valid consent. Supreme Court has clarified that medical negligence will ordinarily be charged under Section 304A of IPC. This is a bailable offence and if proved draws up to 2 years of rigorous imprisonment and fine or both.

OTHER ACTS OF MEDICAL NEGLIGENCE

Besides the Indian Penal Code (1860), there are certain specific Acts which deal with the medical negligence in so far as the criminal liability is concerned and these are briefly discussed hereinafter.

Medical Termination of Pregnancy Act, 1971

It provides that pregnancy can be terminated by a registered medical practitioner, on fulfilment of certain conditions. Under the provisions of this Act, a pregnant woman who has attained the age of 18 years pregnancy can be terminated with her due consent. In case of a woman who has not attained the age of 18 years or who has attained the age of 18 years and is a lunatic, pregnancy cannot be terminated except with written consent of her guardian. Under Section 4, MTP has to be done by a registered medical professional who is qualified to carry out this procedure and also at a place which is recognised and duly registered for medical termination of pregnancy.

The Pre-Natal Diagnostic Techniques (Regulation and Prevention of Misuse) Act, 1994

The Act provides for the regulations of prenatal diagnostic test or techniques for the purpose of detecting the sex of unborn child and its misuse which may lead to female foeticide. Any medical geneticist, gynaecologist, registered medical practitioner or any person who owns a genetic counselling centre or genetic laboratory or a genetic clinic or is employed therein, renders his professional and technical services and who contravenes any of the provision of the Act or Rules shall be punishable with imprisonment for a term up to 3 years which may extend to five years and with fine of 50,000/-. The offence, under this Act, is cognizable, non-bailable and non-compoundable.

Registration of Births and Deaths Act, 1969

The Act provides that every birth has to be registered with the Government and similarly every death has also to be

registered. If not implemented then any professional or organisation who does not comply or who refuses to issue a certificate with effect to the same can be punished as per law.

The Transplantation of Human Organs Act, 1994

The Act provides for the regulation of removal, storage and transplantation of human organs for therapeutic purposes and for prevention of commercial dealing in human organs and matters concerned with or incidental thereto. The Act provides punishment for removal of human organ without authority (Section 18). Section 19 deals with punishment for commercial dealings in human organs. Section 20 deals with residuary offences which have not been provided in other sections of the Act.

Article 21 of the Constitution of India, provides as under:

No person shall be deprived of his life or personal liberty except according to procedure established by Law. The Courts while interpreting Article 21, have held that Article 21 (One of the Fundamental Rights guaranteed by the Constitution), cannot be given a meaningful interpretation unless the Right to Life covers the real meaning of the word 'life', which includes right to proper health, which includes treatment as well. The courts have severely punished the doctors who have failed to provide First Aid or proper treatment for various reasons including want of money, etc. The courts have given a very broad perspective to Article 21 of the Constitution vis-à-vis the medical profession and have applied the dictum of Fundamental Right. Reference here is made of guidelines laid in RN Katara Public interest litigation wherein Supreme Court has laid that every doctor is obliged to provide treatment in emergency.

General Principles of Handling Case of Medical Negligence

These have been lucidly and elaborately explained in the decision of Three Judge Bench of Supreme Court in Jacob Mathew versus State of Punjab and other (2005). Further Justice Markandey Katju in his famous judgment in Supreme Court (Sep 2009), has analysed and described various aspects of medical negligence and cautioned that merely because a complaint has been made that a treatment has been unsuccessful or caused mishap, doctors should not be harassed. Medical professionals operate in a sphere where success cannot be achieved in every case. Very often success and failure depend upon factors beyond the professional's control. The judgment has clearly laid down the procedure in the event of complaint of medical negligence against doctor/hospital whether in District/State/National Consumer Forum or Civil or Criminal Court. The complaint has to be referred to competent doctor/committee of doctors specialised in the field. Only when found by experts that there is a *prima facie* case of medical negligence, should notice be issued to doctor/hospital. He further warned the police officials not to arrest or harass doctor. He emphasised the courts and consumers to base their opinion on the reports, findings of experts in medical science and must not substitute their own views over those of specialist.

INDIAN PENAL CODE 1960

Some clauses relevant to the medical profession are:

Section 304A IPC—Causing Death by Negligence

Whoever causes the death of any person by doing any rash or negligent act not amounting to culpable homicide shall be punished with imprisonment of either description for a term which may extend to 2 years or with fine or with both.

Section 304 IPC—Punishment for Culpable Homicide not Amounting to Murder

Whoever commits culpable homicide not amounting to murder shall be punished with imprisonment for life or imprisonment of either description for a term which may extend to 10 years and shall also be liable to fine if the act by which the death is caused is done with the intention of causing death or of causing such bodily injury as is likely to cause death, or with imprisonment of either description for a term which may extend to 10 years or with fine or with both, if the act is done with the knowledge that it is likely to cause death but without any intention to cause death or to cause such bodily injury as is likely to cause death.

Sections 312-316 of IPC

Sections 312-316 of the Indian Penal Code (IPC) deal with miscarriage and death of an unborn child and depending on the severity and intention with which the crime is committed, the penalties range from 7 years to life imprisonment for 14 years and fine.

Section 312—Causing Miscarriage

Whoever voluntarily causes a woman with child to miscarry shall, if such miscarriage is not caused in good faith for the purpose of saving the life of the woman, be punished with imprisonment of either description for a term which may extend to 3 years or with fine or with both and if the woman be quick with child, shall be punished with imprisonment of either description for a term which may extend to 7 years and shall also be liable to fine.

Section 313 of IPC—Causing Miscarriage without Woman's Consent

Whoever commits the offence defined in the preceding section without the consent of the woman, whether the woman is quick with child or not, shall be punished with imprisonment for life or with imprisonment of either description for a term which may extend to 10 years and shall also be liable to fine.

Section 314 of IPC—Death caused by Act done with Intent to Cause Miscarriage

Whoever, with intent to cause miscarriage of woman with child, does any act which causes the death of such woman, shall be punished with imprisonment of either description for a term which may extend to 10 years and shall also be liable to fine.

But if act is done without the consent of woman, shall be punished either with imprisonment for life or with the punishment above mentioned.

Section 315 of IPC—Act done with Intent to Prevent Child being Born Alive or to Cause it to Die after Birth

Whoever, before the birth of any child, does any act with the intention of thereby preventing that child from being born alive or causing it to die after its birth and does by such prevent that child from being born alive, or causes it to die after its birth, shall, if such act be not caused in good faith for the purpose of saving the life of the mother, be punished with imprisonment of either description for a term which may extend to 10 years or with fine or with both.

Section 316 of IPC—Causing Death of Quick Unborn Child by Act Amounting to Culpable Homicide

Whoever does any act under such circumstances, that if he thereby caused death he would be guilty of culpable homicide, and does by such act cause the death of a quick unborn child, shall be punished with imprisonment of either description for a term which may extend to 10 years and shall also be liable to fine.

THE DRUGS AND COSMETICS ACT

The laws relating to drugs are called the Drugs and Cosmetics Act. They deal with various aspects of manufacture, sale, supply and distribution of drugs including fixation of prices.

The Drugs and Cosmetics Act 1950 (26 of 1950)

The first Act was promulgated in the year 1940. It was amended in the year 1950 and is now known as the Drugs and Cosmetics Act 1950 (26 of 1950). It provides for the control of the sale, supply and distribution of drugs. Drug Controller of India (Ministry of Health), Government of India is responsible for regulation, import and introduction of new drugs as well as permission for drug trials in India. There is a provision for fixing of prices and maximum quantities which can be held or sold.

The Drugs and Magic Remedies (Objectionable Advertisements) Act, 1954

This Act briefly deals with the control of advertisement and in certain cases deals with prohibiting advertisement of certain drugs for magic treatment of certain diseases and disorders. This also lays down the prohibition of misleading advertisement relating to drugs.

CONCLUSION

The subject of ethics, civil, criminal laws governing medical negligence and practice of medicine is vast. Some areas like Medicolegal Cases, Autopsy/Postmortem, Research and Drug Trials, Quality Assurance, Nursing Home Act, Shop and Establishments Act, Patient Safety Concerns, Disposal of Medical Waste are important areas which need detailed discussion but are not covered in this chapter. But it is the responsibility of doctor to know about these rules and regulations so that he can always be on right side of law. We now know that there are a plethora of rules, laws, regulating medical practise and medical negligence the profession need not fear in their practice. The law has always been considerate to the medical profession while dealing with medical negligence and takes due consideration of the circumstances, facility and infrastructure available to the doctor.

The courts have always maintained that doctors have to provide due care with diligence and it is not expected of him to provide the very best which a brilliant doctor may offer but the basic which a ordinary doctor ought to know. The Supreme Court has opined that doctor can only be prosecuted if there is 'gross medical negligence'.

Similarly, the courts have observed an increase in frivolous and vexatious litigations. To avoid these, reverse fines have also been imposed on litigants. Definite guidelines are enunciated to protect the dignity and physical safety of doctors and the para-medical staff working with them.

28.10 Travel Medicine

Yash Pal Munjal

INTRODUCTION AND DEFINITION

'Travel medicine' has gained considerable importance and understanding because of the phenomenal increase in the people travelling across the globe. According to estimates by World Tourism Organisation, international tourist arrivals worldwide during 2010 were approximately one billion and it will escalate to 1.6 billion by the year 2020. Travel is associated with health hazards. It is estimated that 20% to 70% of the travelling population reports a health problem, 1% to 5% seek medical attention and 0.1% to 1% need acute emergency medical care and evacuation. It is estimated that one person in every 100,000 dies due to one reason or the other. Accidents contribute significantly to morbidity and mortality. This has led to the development and progress in 'Travel medicine'.

Travel medicine is an inter-disciplinary speciality concerned not only with the prevention of infectious diseases during travel but also the personal safety of the travellers and avoidance of risks. It also provides information about avoiding health risk to the places and the people where the sick individual is visiting. The Travel Medicine may be considered in the following broad heads:

PRE TRAVEL—GENERAL ADVICE

Any person travelling outside the frontiers of his/her country should seek advice from doctors trained in this speciality or the speciality clinics dealing with travel medicine. This advice ideally should be sought about 8 to 12 weeks before the date of travel and in cases where the travel is planned at the last moment even just before the visit is undertaken. The doctor must understand the following factors if he has to give useful and coherent advice to the travellers:

- Mode of transport
- Destination(s) – demography, disease profile of the country and places to be visited
- Duration and season of travel
- Purpose of travel
- Standards of accommodation and food hygiene
- Behaviour of the traveller
- Underlying health of the traveller

Traveller should be prepared for any eventuality—changes in the travel plans, loss of money, baggage and documents. Therefore, it is suggested that the individual should take an extra supply of medication for about two weeks. A duplicate copy of all the documents should be in the baggage including passport and related documents, detailed history of vaccination and prescription from the doctor, eye glasses and a small telephone directory of numbers for insurance and credit card replacements. A copy of such documents may also be kept at home which can be accessed easily by a relative or friend.

Every traveller should preferably have a health travel insurance, and must understand clearly the extent to which travel related reimbursement is permissible and expenditure can be incurred. They should carry with them a 'first aid kit' so that they can attend to themselves in an emergency. The contents of the basic medical kit (first aid items) are adhesive tape, antiseptic wound cleanser or soap, bandages, scissors, safety pins, emollient (lubricant) eye drops, insect repellent, insect bite treatment, antihistamine tablets, oral rehydration salts, antidiarrhoeal medication and common antibiotics which the traveller can use himself in case of diarrhoea, infections of the skin and soft tissue, respiratory and urinary tract along with antimalarial medication, antibacterial ointment, antifungal powder and insecticide besides adequate supplies of condoms and oral contraceptives. Special precaution has to be taken for travellers at the extreme of ages, pregnancy and associated disability. Some of the specific issues are discussed in the following paragraphs.

SPECIFIC ADVICE

Accidents

Accidents are one of the major causes of disability and mortality. This gets compounded with the varying 'On Road Travelling Norms' followed in other countries. Drinking and driving should not be mixed. The traveller should not drive a particular type of vehicle which he is not conversant with. It is also advisable to have protective gear especially while riding two-wheeler transport.

Animal Exposure

Exposure to animals at places of travel can increase the risk of zoonotic diseases as well as rabies. Rabies is endemic in some under-developed countries and the traveller is advised not to engage contact with unfamiliar animals. Rabies exposure prophylaxis may be useful for travellers who are on long visits to some of the endemic areas.

Medicinal Interactions

The traveller should be conversant with all the drugs which he is carrying and any drug—drug interaction thereof. It is useful to remember that antacids and antidiarrhoeal drugs frequently interfere with the absorption of other medications. While purchasing extra supplies in other countries, be careful with regard to quality of drugs. Therefore, always purchase medicines from a good quality store and get a receipt.

Sexually Transmitted Diseases

Travellers become uninhibited during vacations abroad when they may engage themselves in unprotected sexual activity. Therefore, it is important that they carry with them good quality and adequate supplies of condoms while travelling. Women should carry oral contraceptive pills. STD organisms are antibiotic resistant in some of the countries, therefore absolute care and protection is a must.

Exposure to Ultraviolet Radiation

In tropical countries, or at high altitude, the sun exposure can be more intense than expected. Travellers should use broad

spectrum sun screen creams with UVA and UVB protection. Tetracycline and ciprofloxacin which are often recommended for travellers' diarrhoea or malaria prophylaxis can cause sun-induced rashes. In addition, sun glasses may be useful.

Swimming

Travellers are advised to undertake swimming only in hygienic and chlorinated pools because the other waters may be contaminated with bacteria from sewer or industrial waste, etc. Travellers must note about the risk of schistosomiasis in the area. If the traveller is bathing in questionable sources of water he should dry up vigorously and as rapidly as possible. Protection of feet must be ensured.

High Altitude

Travelling to places where the altitude is above 10,000 feet may cause acute mountain sickness. This usually presents with dizziness, headache, fever, chills or vomiting. Severe illness includes high altitude pulmonary oedema, confusion and extreme lethargy (high altitude cerebral oedema). The travellers are advised to travel at high levels slowly, acclimatise themselves to high altitudes and should not undertake strenuous activity.

Use of alcohol and tobacco should be significantly reduced. For minor sickness acetazolamide can be used. Rest and acclimatisation may relieve discomfort. If extreme symptoms appear, traveller must be evacuated to lower levels as quickly as possible.

Arthropod-Borne Diseases

This can be a reason for morbidity and prolonged sickness. A bite by an insect or reptile may cause pain or inflammation at the site of the bite or sting. Certain generalised reactions are known due to the venom injected or allergic reaction. Moreover arthropods can transmit serious potentially life-threatening diseases including malaria, yellow fever, dengue haemorrhagic fever, filariasis (mosquitoes), viral encephalitides (mosquitoes, ticks), onchocerciasis (black flies), leishmaniasis (sand flies), African trypanosomiasis (tsetse flies), American trypanosomiasis or Chagas diseases (reduvid or kissing bug), plague and tungiasis (fleas), typhus (fleas, lice, ticks) and relapsing fever (lice and ticks).

Arthropods vary according to different geographical conditions. Vaccines are available to protect individuals against some of these illnesses. Therefore, it is preferable to use them but the advice must be tailored to the geographical area to be visited.

Following precautions and preventive steps can be helpful:

- Avoid walking in the countryside especially in the evening. Always wear light coloured long sleeved shirts and long pants with preferably gum boots. Wear footwear at all times and always shake footwear before wearing.
- Use insect repellents, bed nets and good camps.
- Sleep in air-conditioned or well-screened rooms or under bed nets in areas where arthropod borne diseases are present.
- Prior to sleeping, spray the room/net with anti-insecticide spray. The net should be of good quality and should cover the bed on all sides.
- Avoid perfumes, scented creams, lotion, etc.

Malaria

Travellers visiting countries which are considered malarial zones are advised to take prophylactic treatment. This treatment has to be based on the type of Plasmodia and their resistance patterns in the area of travel. The broad outline for prophylaxis is given in the **Table 1**.

Table 1: Medications and Regimes for Malaria (Prevention)

Name of Drug	Dose	Side-effects
Chloroquine Phosphate (Chloroquine sensitive areas)	Paediatric dose: 5 mg per kg per week Adult: 500 mg once a week Start 1 week before travel and continue 4 weeks after travel every week on same day of the week	Side effects are uncommon and could be dizziness, headache, nausea and vomiting Can exacerbate psoriasis Discontinue medicine if visual changes occur
*Mefloquine (Areas with Chloroquine resistance)	Paediatric dose: 5 mg per kg if weight is less than15 kg Adult: 250 mg once a week Start 1 to 2 weeks before travel and continue 4 weeks after the travel. Take it after the travel. Take it after food and with plenty of water.	Dizziness, vomiting, anxiety, restlessness, ectopics. May exacerbate already existing psychiatric disturbances or depression. Can trigger and interact with anti-epileptic and cardiac drugs. Do not use in major psychiatric disorders, seizure disorders and cardiac conduction defects.
*Doxycycline Hyclate	100 mg/dL Start 1 to 2 days before travel and continue 4 after the travel	It can cause skin rashes and an intense burn with exposure to sun weeks (use extra sun screen) and vaginitis in women. Do not take with milk products or antacids. Do not use in children below 8 years, pregnant women and nursing mothers.
*Atovaquone/ Proguanil	Weight based for children 250 mg/100 mg/dL beginning 1 to 2 days before and discontinue 7 days after. Take with food or milk	Side effects are uncommon Can cause severe or uncontrolled vomiting, diarrhoea, fever, nausea, stomach pain, loss of appetite, dark urine, clay coloured stools, jaundice or mouth sores. Do not use in renal failure, pregnancy or nursing mothers. Use with caution in patients with liver disease
*Chloroquine Phosphate + Proguanil	Same as above This combination may be started 1 to 2 days before entering and continued for 4 weeks after arrival	Same as above

** Useful in resistant P. falciparum.*

Traveller's Diarrhoea

Traveller's diarrhoea has been defined as the occurrence of three or more loose stools each day or any number of loose stools accompanied by abdominal cramps, fever, vomiting occurring among travellers usually from developed to developing countries. It affects 20% to 70% of travellers when travel is confined to 2 weeks or less. Developing countries of Asia, Africa and Latin America are high risk areas. Intermediate risk areas are Caribbean Islands, Israel, Southern Europe, South Africa and China while North America, Europe, Japan and Australia are low risk areas.

Incidence is highest among very young (40%) presumably owing to increased contamination and decreased immunity. Incidence is high in the 15 to 29 years age group (29%), perhaps owing to adventurous style travel and the ingestion of higher volume of potentially contaminated food. Unpeeled fruits, uncooked vegetables (salads) and cooked meals that have been stored at inadequate temperatures or cooked at insufficient temperatures are believed to be main source of enteric pathogens for travellers. Onset of diarrhoea is usually within the first week of travel. Duration of illness usually is short and self limiting to 24 hours in 20%, 2 to 7 days in 14% to 16% and 1 week or longer in 20% of cases. The average individual will experience four loose stools associated with abdominal cramps in 20% to 60% of cases, bloody stools (15%), fever (10%) and vomiting (10%). Clinical characteristics of illness are related to organisms responsible.

Prevention

- Drink safe water.
- Avoid uncooked cold food which is not boiled or steaming hot.
- Avoid food from street vendors
- The safe beverages include:
  1. Boiled water beverages—tea or coffee.
  2. Carbonated bottled drinks (keep in mind that large intake of mineral water can cause mild diarrhoea from the cathartic effect of the minerals).
  3. Canned/boxed fruit juices.
  4. Bottled/canned alcohol containing beverages—beer or wine in moderation.

Recommendations for water treatment include the following:

- Boil and cool water before drinking.
- Use iodine tablets as directed. Be careful if using for pregnant women as it may interfere with foetal development.
- Use chlorine dioxide tablets as directed.
- Use a portable water filter available at Sports Goods Stores or General Stores. Several versions of portable UV light sources are available including litre water bottles with UV light or filters built in.

Treatment

Initial treatment should consist of using binders like bismuth and/or loperamide. In case it is severe and associated with fever, antibiotics may be used. If not controlled and/or associated with fever treat like any other acute infective diarrhoea.

Vaccinations for Travellers

Vaccinations for people travelling abroad are generally safe. The advice regarding vaccination varies according to the geographical area to be visited. All vaccinations for travellers are listed in **Table 2**.

The details about the dosage and frequency of immunisation are given in the Chapter on 'Adult Immunisation' (Chapter 7, Section 28).

Pregnant Traveller

Pregnant women have a less effective immune response which makes them more vulnerable to have severe or potentially fatal complications from infections, such as malaria, typhoid fever and amoebiasis. The pregnant traveller should get current and specific advice from experts who can contribute significantly to her safety, health and her future new born. Civil aircrafts do not allow travel beyond 36 weeks of pregnancy.

Table 2: Vaccinations for Travellers

Category	Vaccine	
Routine Vaccination	Diphtheria, Tetanus and Pertussis	Pneumococcal Disease
	Hepatitis B	Poliomyelitis
	Haemophilus influenzae Type B	Rotavirus[a]
	Human Papillomavirus[a]	Tuberculosis[c]
	Influenza[b]	Varicella
	Measles, Mumps and Rubella	
Selective use for travellers	Cholera	Rabies
	Hepatitis A[d]	Tick-Borne encephalitis
	Japanese Encephalitis[d]	Typhoid Fever
	Meningococcal Disease[d]	Yellow Fever[d]
Required Vaccination	**Yellow Fever (See Country List)	Meningococcal Disease and Polio (required for Saudi Arabia specially for Haj pilgrims)

*** It is applicable in certain countries to consult.*

a. These vaccines are currently being introduced in some countries.

b. Routine for certain groups and risk factors, selective for general travellers.

c. No longer routine in most industrialised countries.

d. These vaccines are also included in the routine immunisation programme in several countries.

Avian Flu

The travellers going to areas affected by H5N1 virus must have received seasonal influenza vaccine. They should avoid all direct contact with birds including domestic poultry or touching surfaces contaminated with poultry secretions. All food from poultry including eggs should be cooked thoroughly. Egg yolk should not be liquid or runny. Seek immediate medical help if affected with fever, cough, rhinorrhoea, difficulty in breathing, etc.

SOME OTHER TRAVEL RELATED COMMON AILMENTS

Jet Lag

'Jet lag' is a syndrome consisting of symptoms, such as fatigue, weakness, drowsiness and irritability. It is caused by disruption of circadian cycle. Various unproven but widely recommended measures include increased hydration, exercising (i.e. walking in the plane), administration of melatonin and administration of short acting hypnotics.

Diet and nutrition play an important role in the management of jet lag. High carbohydrates and protein diet is advocated. Alcohol and caffeine should be used in moderation.

Motion Sickness

It is caused by travelling and consists of pallour, cold sweating, nausea and vomiting. The drugs with a proven record of safety and efficacy are scopolamine, antihistamines (dimenhydrinate, meclizine) and dextroamphetamine. Of these drugs, the transdermal scopolamine patch is the most effective with less side effects.

Table 3A: Insulin Adjustment Schedule – Eastbound Travel Across Six or More Time Zones

Dose Schedule	Day of Departure	First Morning at Destination	10 hr after Morning Dose	Second Day
Single dose schedule	Usual dose of Insulin	Two-thirds of usual insulin dose	Test blood glucose. Give remaining one-third a.m. dose if glucose is >240 mg/dL	Usual dose
Double dose schedule	Usual a.m. and p.m. doses of insulin	Two-thirds of a.m. dose	Test blood glucose. Give usual evening dose and remaining one-third morning dose if glucose >240 mg/dL	Usual two doses

Table 3B: Insulin Adjustment Schedule – Westbound Travel Across Six or More Time Zones

Dose Schedule	Day of Departure	Test Blood Glucose 18 hr after a.m. Dose	First Morning Destination
Single dose schedule	Usual Insulin dose	One-third of usual morning insulin dose followed by snack or meal if blood glucose is >240 mg/dl	Usual dose of insulin
Double dose schedule	Usual a.m. and p.m. dose (10 to 12 hours after the morning dose)	As above	Usual two doses of insulin

Travel for Operated Patients

During ascent in air travel there is expansion of gases in body cavities to the tune of about 25%. It is important that at least 10 days should have elapsed between any intrathoracic or intra-abdominal surgery before flying. Similarly, minor dental procedures like root canal therapy or fillings are advised to wait for approximately 24 hours before flying.

Pulmonary Disease

The presence of chronic pulmonary disease, such as bronchitis, emphysema and asthma may limit their pulmonary gas exchange. Such conditions could become exacerbated even within the pressurised cabin of an airline. The cabin pressures maintained within commercial airline do not necessarily conform to those occurring at sea level.

In these patients, pulmonary function should be maximised to maintain the best FEV1 possible by continuing bronchodilators and corticosteroid therapy before and during flights. If the traveller is unable to tolerate the lowered cabin pressure, request for supplemental oxygen should be made.

Cardiac Disease

Most of the in-flight deaths are caused by cardiac problems, such as myocardial infarction or cardiac arrest. The emergency medical kit of airlines is generally inadequate. The availability of external defibrillator on the airlines and resuscitation skills among flight attendants may avert approximately 50% of these deaths, which occur due to ventricular fibrillation. Further cardiac patients should carry all medications, a copy of the recent ECG and those with pacemakers should carry ECG performed with and without pacemaker activation.

Diabetes Mellitus

All diabetics should carry medications, syringes, needles and snacks with them. They must carry a card mentioning their physician's name, telephone number, type and dose of insulin/other medication used. **Tables 3A and B** show the changes in dose schedule during east or west bound travel.

SPECIAL HEALTH CONSIDERATIONS FOR TRAVELLERS WITH CHRONIC DISEASES

The following broad principles must be kept in mind for advising travellers with chronic diseases. Asses status of disease and management to be followed during travel.

Medical Examination after Travel

It is advisable for all the travellers to have a medical examination on their return, if especially they have an existing chronic disease, such as COPD, diabetes mellitus, chronic respiratory disease or on anticoagulants. If they develop any sickness following their return home or they had been treated for any illness during travel especially malaria or any serious infectious disease or patients who have travelled for more than 3 months in a developing country should have medical examination. Again, it is pertinent to note that the traveller should provide adequate information about the place, duration of visit, pre-travel infection and malaria prophylaxis. Malaria may be considered an emergency especially if a person develops fever on his return and must be reported as well as proper consultation taken from the doctor.

CONCLUSION

Travel is undertaken for leisure, business, visiting family and relatives. Therefore, it is imperative that one must stay healthy and the traveller should get vaccinated, examined, and get medical insurance done before travelling to a particular country. He must see the Official Site for any ongoing raging or infective epidemic and demographic disease profile. Post travel medical examination is equally important as pre-travel medical advice.

28.11 Nanotechnology and Nanomedicine

Ramchandra D Lele

INTRODUCTION

The word 'nano' is derived from the Latin word which means 'dwarf'.

The prefix 'nano' refers to one-billionth. When applied to linear measurement, a nanometer is one-billionth of a meter. The term nanotechnology is now used to refer to the creation of new objects with nano-scale dimensions between 1 and 100 nanometers. The width of a DNA molecule is approximately 2.5 nm. Most proteins are in the range of 1 to 15 or 20 nm. The width of cell membranes is in the range of 6 to 10 nm.

Nanotechnology was first predicted by Nobel Laureate Richard Feynman in 1959. The 10^{12} cells in the human body themselves are very complex and efficient nano-machines and chemists and biochemists have been working at the nanoscale for some time without using the 'nano' lable. Most research in molecular biology already takes place on a nanoscale. Most areas of nanoscience aim to learn from biological nanosystems.

The invention of light microscope (1632) allowing magnification × 400 diameters, apart from revealing micro-organisms, opened the vista of study of living matter at micrometer size establishing the cell as a unit of life, and specific cell types for specific functions and the concept of cellular pathology. The invention of electron microscope by Ernest Ruska in 1931 (Nobel Prize 1986) allowing magnification X 12,000 diameters, and freeztech EM (X 95,000 diameter) led to the identification of subcellular organelles—lysosomes, peroxisomes, Golgi apparatus, endoplasmic reticulum, mitochondria and nuclear components chromosomes, and the concept of lysosomal, mitochondrial and chromosomal disorders. In the brain, EM revealed the synaptic vesicles (300 to 600 Å) which store neurotransmitters and microtubules as conveyors of a two way traffic between a nerve cell body and its dendrons and axons (one Angstrom is 10 nm).

The invention of the scanning tunneling microscope in 1981 by Binig and Rohrer (Nobel Prize 1986) allowed the measurement of and manipulation of individual atoms on a surface. Scanning probe microscopes now extensively used in bio-scientific research are so sensitive that they can detect differences in one base pair in DNA hybridisation. Nanoscale oligonucleotide arrays for gene expression research encompassing the entire human genome on a single chip eliminates the need for labeling DNA strands which simplifies the process of diagnosis. Another Nobel Prize winning breakthrough in nanoscience was the discovery of spherical buckminister fullerenes by Kroto *et al.* in 1985—compounds containing 60 atoms of carbon arranged in a lattice of hexagonal and pentagonal specific connections sometimes likened to the surface of a soccer ball. The C60 fullerenes are 1 nanometer in diameter. Fullerenes have captured the imagination of pharmaceutical research for a number of their unique properties as drugs or components of targeted drug delivery (**Table 1**).

Some years after the discovery of fullerenes, carbon nanotubes or basically open-ended buckyballs were invented, which led to numerous potential scientific and commercial applications including novel display units for computers. Some nanotubes have superconducting properties which are utilised in the new generations of computer systems and electric transmission systems.

Beyond biology, there is enormous interest in nanotechnology. The properties of nanoscale objects and material are quite different from the properties of the same chemical materials created with larger dimensions, as a result of the fundamental principles of quantum physics. Strength, electrical conductivity melting point, colour, and optical and magnetic properties are all potentially affected (Thrall 2004).

There is growing interest in the use of biomolecules as components in electrical circuits and computing systems to permit further miniaturisations with increased computational capacity. The feasibility of using DNA hybridisation to solve complex mathematical problems has been demonstrated at a proof-concept level.

DNA is more than just the secret of life. DNA is now a versatile component of nanoscopic structures and devices. DNA molecules of long length can be made with a sequence of building blocks chosen at will, enabling us to take new paths not yet taken by Nature.

Researchers at Mc Gill University Chemistry Department Montreal have created the first examples of DNA nanotubes that encapsulate and load cargo and then release it rapidly and completely when a specific external DNA strand is added.

DNA machines with moving parts are employed as nano-mechanical sensors, switches and tweezers as well as more elaborate robotic functions. Nanorobots could actually be programmed to repair specific diseased chromosomes in cells or for delivery of Si RNA. Scientists have developed methods for detecting micro RNA from living cells as potential therapeutics for silencing cancer and disease-related genes.

Nanotechnology is the art and science of manipulating individual atoms to create useful materials and devices on a scale of 1 to 100 nanometers (10^{-9}) and to create miniature systems with novel functionality, such as nanorobots.

Nanomaterials are biomaterials used, for example, in orthopaedic or dental implants or as scaffolds for tissue engineered products. Their surface modifications or coding greatly enhance the biocompatibility. These materials can be subclassified into nanocrystalline and nanostructured materials.

Nanocrystalline materials are used in drug encapsulation, bone replacement, prostheses, e.g. artificial limbs, facial prosthetics, neuroprosthetics and implants.

Super paramagnetic iron oxides (SPIOs) also known as monocrystalline iron oxide nano particles (MIONs) have shown

Table 1: Nanotechnology Relevant to Medicine

Nanotechnology	
Nanomaterials	**Nano-devices**
Nanocrystalline	NEMS/MEMS
Nanostructured	Respirocytes
Polymer	Microarrays
Nanoparticles 10 mm	
Dendrimers 1.5 nm	
Micelles 10 to 100	
Drug-Conjugates	
Non-polymer	
Carbon nanotubules 1 to 100 nm	
Metallic nanoparticles <100 m	
Quantum dots 1 to 9.5 m	
Silica nanoparticles	

promise for a number of magnetic resonance imaging applications both as naked particles and as magnetic lables. SPIO particles remain in circulation for long time permitting MRI imaging of arteries and veins. In prostate cancer using lymphotropic superparamagnetic nanoparticles of 2 to 3 nm size, micrometastases of 2 nm size in retroperitoneal lymph-nodes of normal size can be detected by MRI.

Nanostructred materials provide special shapes or functionality, e.g. Quantum dots, dendrimers, fullerenes and carbon nanotubes, metallic and ceramic nanoparticles (silica, alumina, silica-coated lipid miscalls).

Nanodevices are miniature devices in the nanoscale some of which include nano and micro electro-mechanical systems (NEMS & MEMS), microfluidics (control and manipulation of micro or nanolitres of fluids) and micro-arrays (different kinds of biological assays, e.g. DNA, protein, cell and antibody). Examples include biosensors and detectors to detect trace quantities of bacteria, airborne pathogens and some intelligent machines like respirocytes, biovores and vasculoid. Medical nanodevices can be implanted or injected into the blood stream to monitor wellness and to automatically repair systems that deviate from normal.

C60 fullerenes (**Figure 1**) have 60 potential carbon binding sites compared to only six on a benzene ring. This offers opportunities to use fullerenes as scaffolds for complex nanoassemblies, e.g. attachment of targeting antibodies along with chemo-therapeutic agents or radioactive materials for the treatment of cancer. Because of their rigidity, fullerenes can be complexed with other molecules by using precise measurements and configurations based on the properties of the target, to achieve targeted therapy.

Carbon nanotubes (**Figure 2**) are hexagonal networks of carbon atoms 1 nm in diameter and 1 to 100 nm in length, as a layer of graphite rolled up into a cylinder. Nanotubes can be single walled (SWNT) or multiwalled (MWNTs), have ordered structure with high aspect ratio, ultra light weight, high mechanical strength, high electrical and thermal conductivity and high surface area, which makes them useful for diagnostic as well as drug delivery systems. Nanotubes are used to construct nanotweezars proteins, antibodies or DNA can be conjugated to biotinylated SWNTs for biomedical applications.

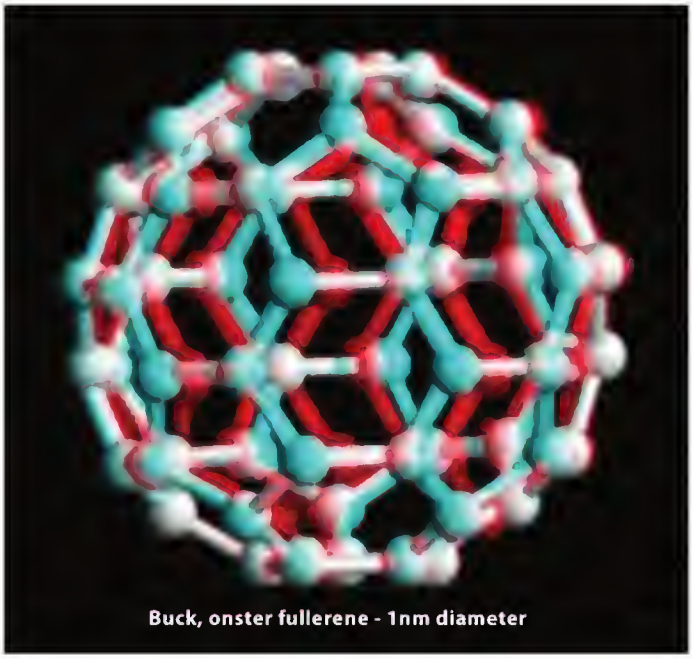

Figure 1: C60 fullerenes.

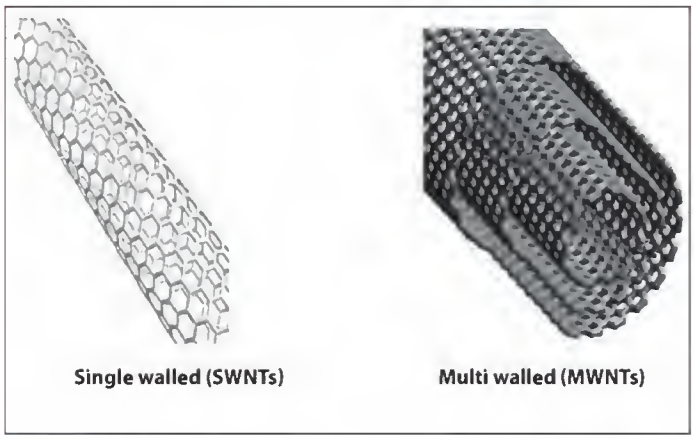

Figure 2: Carbon nanotubes.

Metallic nanoparticles <100 nm because of their easy surface functionalisation are useful as biosensors (gold or silver nanoparticles linked to DNA, proteins, peptides and sugars). They have been used for drug delivery, bioassays, detection and imaging, as an alternative to quantum dots.

Gold nanoparticles (**Figure 3**) are very good at absorbing and scattering light. 35 nm size gold particles tagged to EGFR-Ab can be sprayed on a tissue biopsy specimen. They adhere to cancer cells with 600% greater affinity than normal cells. With a simple microscope and white light cancer cells will show up as shining particles.

Silver nanoparticles (7 to 20 nm) kill Gram-negative bacteria effectively than Gram positive bacteria and also have good antifungal activity when introduced into dressings for wound healing. They also show good anti-inflammatory activity, suppress MMP and TGFβ1 which accelerate wound healing without leaving a scar.

Nanoparticles of iron are non-irritant to the GI tract hence ideal treatment for iron deficiency anaemia.

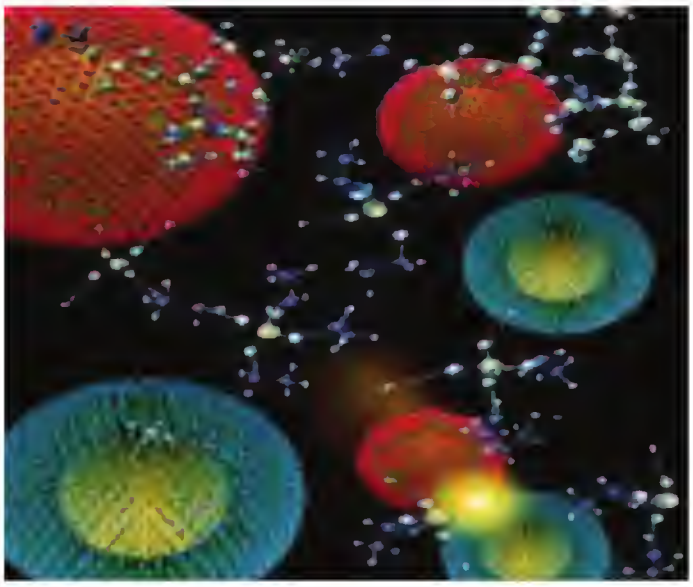

Figure 3: Surface functionalised gold nanoparticles.

Quantum dots (QD) (Figure 4) (2 to 9.5 nm) are semiconducting materials with a semiconductor core (CdSe) coated by a shell (e.g. ZnS) to improve optical properties and a cap enabling improved solubility in aqueous buffers. They glow when stimulated by ultra light. They can be linked to DNA molecules or proteins to form long-lived probes. They can track biological events through biological pathways thus providing diagnosis at the molecular level, such as early detection of mutagenic DNA changes—bioimaging or real time monitoring or tracking of intracellular processes by optical imaging and MRI, detection and analysis of bio-molecules, immunoassays, DNA hybridisation and non-viral vectors for gene therapy, transport vehicles for DNA, proteins, drugs or cells and therapeutic tools for cancer treatment.

Silica-coated nanoparticles (Lipid micelles) can be used for directed cancer therapy. Lipid micelles containing LHRH as a targeting agent can deliver iron oxide particles to LHRH-positive cancer cells.

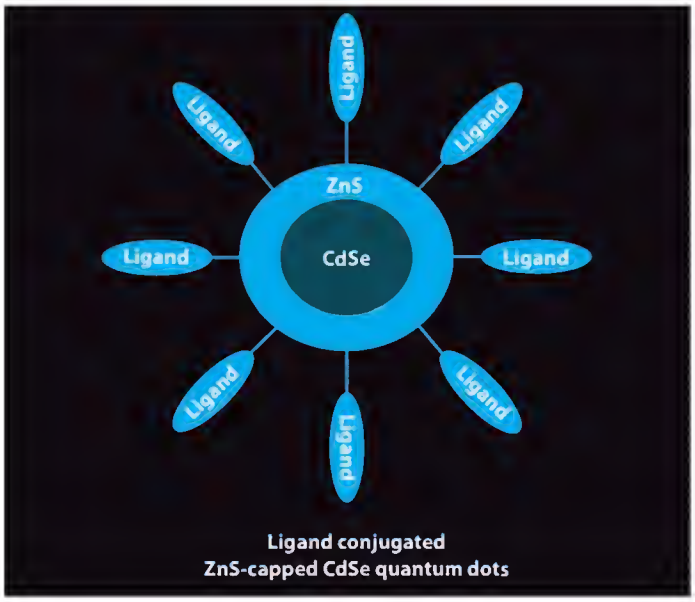

Figure 4: Quantum dots.

Polymeric nanoparticles are colloidal carriers 10 nm to 1 μm size are ideal for controlled and targeted drug delivery due to some inherent properties like biocompatibility, non-immunogenicity, non-toxicity and biodegradability.

Dendrimers (Figure 5) are hyperbranched 1 to 5 nm tree-like structures providing vast surface area and have compartmentalised chemical polymer. They serve as versatile nanoscale platforms for creating multi-functional devices capable of detecting and treating cancer through targeted drug delivery. A single dendrimer can carry a molecule that recognises cancer cells, another molecule, a therapeutic agent that can kill these cells and a third molecule recognising the signals of cell death. They can be tailored or modified into bio-compatible compounds with high biopermeability and low cytotoxicity. Their hollow interior permits delivery of drugs, vaccines, MRI contrast agents, metals and genes to targeted sites.

Polymeric micelles (Figure 6) (10 to 100 nm) ampiphilic block copolymers have hydrophilic surface preventing non-specific uptake by reticuloendothelial system. These dynamic systems are used for systemic and controlled delivery of water-insoluble drugs at target sites.

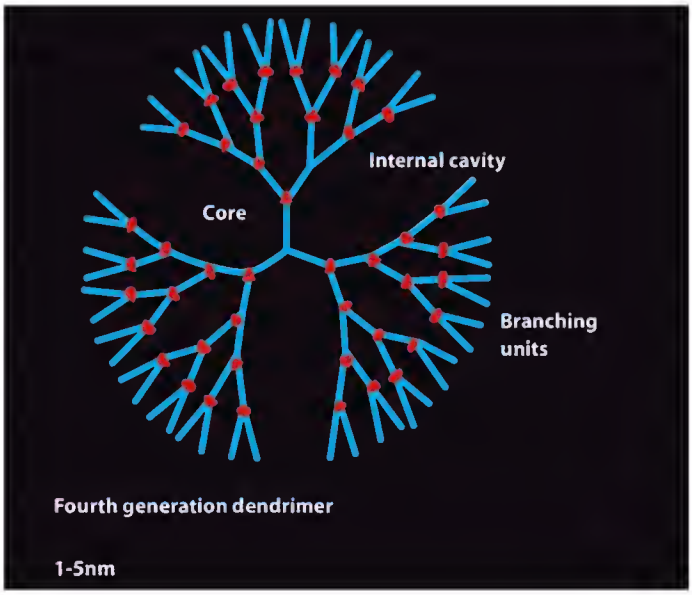

Figure 5: Fourth generation dendrimers.

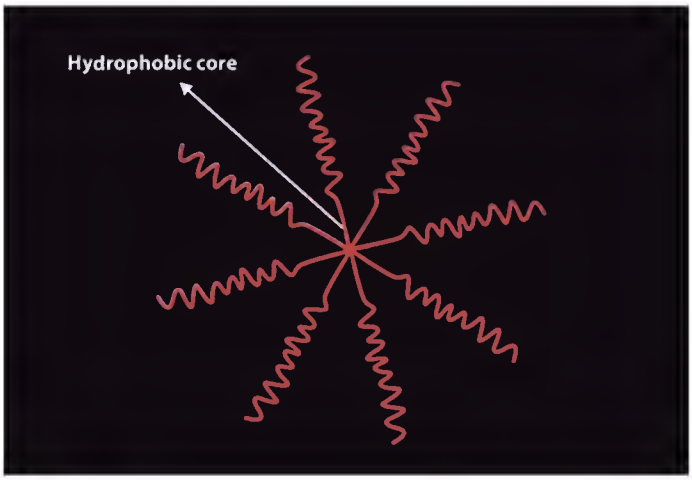

Figure 6: Polymeric micelles.

Polymer drug conjugates (**Figure 7**) are designed to increase the overall molecular weight by conjugation with low molecular weight drugs which facilitates their enhanced permeation and retention (EPR) in tumours taking advantage of leaky vasculature. Nanocarriers can alter the biodistribution and pharmacokinetic parameters of drugs.

Folate nanoparticles have high specific affinity for human cancer cells hence they improve uptake of encapsulated drugs.

Nanocarriers overcome the problem of poor bioavailability, short half-life, insolubility, instability and undesirable side effects and toxic effects of anti-cancer cells.

Liposomes (**Figure 8**) (50 to 100 nm) are extensively used for novel and targeted drug delivery. Small unilmellar vesicles (SUV) are less than 100 nm in size while large unilamellar vesicles (LUVs) are larger than 100 nm. Multilamellar vesicles (MLVs) consist of several lipid bilayers separated from one another by aqueous spaces after ranging from a few hundred to thousands of nm in diameter variety of surface modification approaches permit controlled and targeted drug delivery in cancer, leishmaniasis, ophthalmic condition, etc.

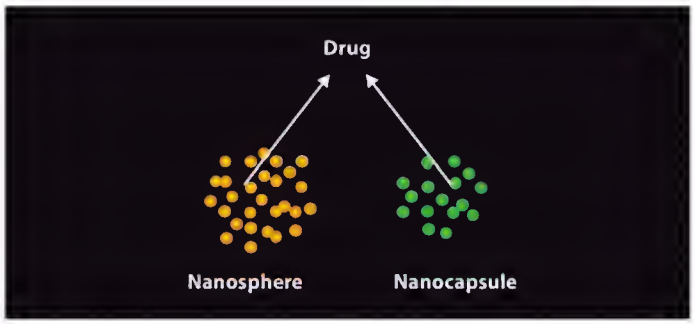

Figure 7: Polymer drug conjugates.

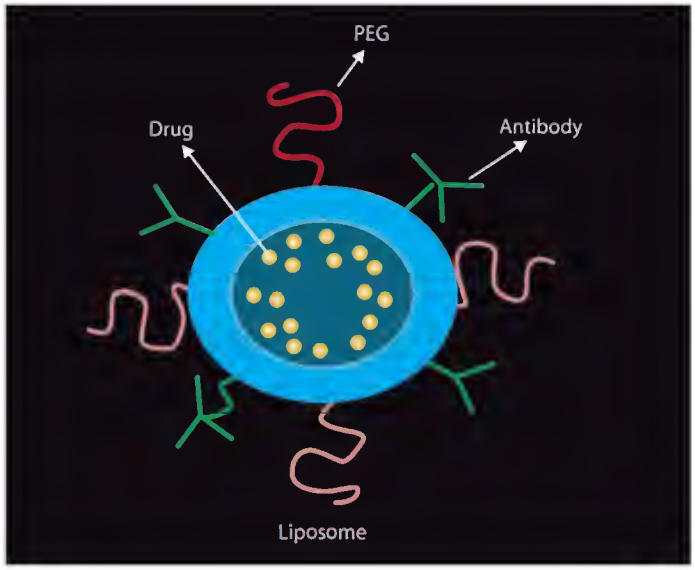

Figure 8: Liposomes.

MEDICAL APPLICATIONS OF NANOTECHNOLOGY

Nanomedicine is the medical application of nanobiotechnology which opens up new ways to diagnose and treat disease and repair damaged cells and tissues. There is an increasing ability to manipulate individual molecules and to combine biomolecules with other nanoscale structures. This ability offers the opportunity for unlimited new diagnostic and therapeutic applications.

Medical nanodevices can be implanted or injected into the blood stream to monitor wellness and to automatically participate in the repair of systems that deviate from normal.

Nanopore fillers show superior performance compared to micropore filters. Improved filtration in drug production is designed for better purity, sterility and apyrogenicity.

Nanotechnology is putting the goal of building a 'lab-on-a-chip' within reach. By using very small channels, only nanogram quantities of analytes and reagents are required. Such device will make sophisticated tests widely and immediately available at lower costs in the clinic, at home, or at patient's bed side.

Nanotechnology has the power to radically change the way cancer is diagnosed, imaged, and treated. There are ongoing efforts to design novel nanodevices capable of detecting cancer at its earliest stage, pinpointing its location within the body and delivering anticancer drugs specifically to malignant cells, totally avoiding normal cells, and to monitor the effectiveness of therapy.

Nanoscale devices smaller than 50 nanometres can easily enter most cells, while those smaller than 200 nanometres can transit out of blood vessels. Hence, they can interact with biomolecules on both the cell surface and within the cytoplasm delivering therapeutic agents within the target cell or even within specific organelles, such as mitochondria, Golgi apparatus. Dendramers are nanoscale delivery devices which can deliver DNA into cells for gene therapy. Unlike viral vectors they do not evoke an immune response. Despite its small size a nanoscale device is capable of holding tens of thousands of small molecules, such as drugs or contrast imaging agents. Even toxic drugs can be delivered at much smaller doses in a controlled and time release manner.

In humans there is only one mechanism to repair UV induced DNA damage while simpler organisms have two or sometimes three repair systems. Using nanoparticle biosensor technology we can supply the missing first step (glycosylase) to enhance DNA repair in human cells.

Nanocarriers penetrate better the leaky tumour cell membrane with 100 to 1,000 nanometre sized pores.

Molecular Biosensors for Nanodelivery

Moleular biosensors are designed to sense their environment within a cell and minimally perturb that cell's basic function, hence they are frequently used inside living cells to monitor basic cell biochemistry in response to drugs, environmental factors, etc.

Molecular biosensors provide sensing extracellular and intracellular environments and to provide feedback for action, such as drug or gene delivery.

Conventional drug delivery systems have no feedback control. Molecular biosensors provide feedback control for stable expression of a therapeutic gene such as DNA repair enzyme. For example, a biosensor sensing radiation-induced oxidative stress and DNA damage can initiate through a synthetic ARE transcription of DNA repair enzyme in the damaged cell only (and not in normal cells).

Similarly, for the treatment of Hepatitis C virus, targeted tetracycline transactivator protein based biosensor seek out infected liver cells, with HCV viral E protein on its surface and deliver ribozymes (molecular scissors) to the IRES region of the virus inside the living cell so that it cannot make new virus. This approach has much fewer side-effects than the current interferon-ribavirin therapy which at best succeeds in only 30% of cases.

Nanoshell Associated Photothermal Therapy (NAPT)

Nanoshells have a core of silica coated with an ultra thin metallic layer, usually gold. By adjusting the core and shell thickness, nanoshells can be designed to absorb and scatter light at a desired wave length. Using nanoshells that absorb light in the near infrared (NIR) region and then convert it into heat (40°C), and delivering them specifically to cancer cells via enhanced permeability and retention (EPR) effect, selective photothermal ablation can be achieved in a non-invasive way using a laser in the NIR region.

Nanoshells also have an interesting application in the treatment of insulin-dependent diabetes mellitus. Instead of several daily injections of insulin, the patient will use a ball point pen size infrared laser to heat the skin wherein a nanoshell polymer containing insulin has been injected. The heat from the nanoshell will cause the polymer to release a pulse of insulin. The nanoshell polymer system could remain in the body for months. (Nanospectra Bioscience www.nanospectra.com).

Molecular Nanotechnology (MNT)

DNA-based nanomachines are computer-controlled molecular tools, such as nanomoters, and molecular tweezers, much smaller than a human cell. Nanorobots will function as artificial red cells (respirocytes), artificial macrophages (microbiovore), artificial platelets, mitochondria etc.

Molecular nanotechnology (MNT) or nanorobotics will allow performance of direct invivo molecular surgery on individual human cells. The ability to design, construct and deploy large numbers of microscopic medical nanorobots will make this possible. A nanorobot can sense hypoxia and deliver VEGF at site for neoangiogenesis (**Figure 9**).

It is an interesting thought that the human body is full of micro-robots in the form of endothelial progenitor cells (EPCs), red blood cells, leucocytes (neutrophils, monocytes/macrophages, lymphocytes) and fibroblasts, that are constantly moving inside our bodies, repairing damaged tissue, attacking invading microbes, gathering foreign particles and transporting them to various organs for disposal from the body. Hence, it is possible to develop prototype microscale assemblers using micro-electromechanical systems (MEMS) and nano-electro-mechanical systems (NEMS). Interesting examples are: 'Microbiovore' an artificial white blood cell, 'respirocyte' an artificial red blood cell, vasculoids and artificial platelets.

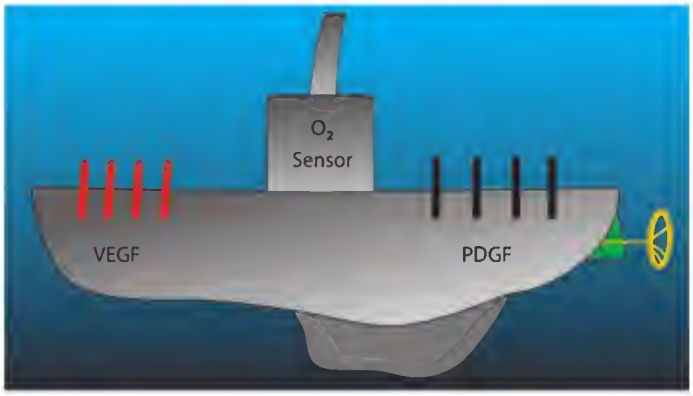

Figure 9: Nanorobot.

VEGF = Vascular endothelial growth factor; PDGF = Platelet-derived growth factor.

Microbiovore (**Figure 10**), an artificial white blood cell, is an oblate spheroidal nanomedical device measuring 3.4 μ diameter along its long axis and 2 μ diameter along its short axis, consisting of 610 billion precisely arranged structural atoms in a gross geometric volume of 12 μ^3, and a dry mass of 12.2 picograms. It is 80 times more efficient in phagocytosis than macrophages, in terms of volume/second digested per unit volume of phagocytic agent. During each cycle of operation the target bacterium is bound to the surface of the microbiovore in the blood stream like a fly on fly paper via species—specific binding sites, and transported to the ingestion port. After sufficient mechanical mincing it goes to a digestion chamber wherein a pre-programmed sequence of 40 engineered enzymes are successively injected and extracted six times progressively reducing the morcellate ultimately to monoresidue aminoacids, mononucleotides, glycerol, free fatty acids and simple sugars. These simple molecules are then harmlessly discharged back into the blood stream through an exhaust port, completing the 30-second cycle. Microbiovores can clear the most severe septicaemia within a few hours or less time compared to weeks by the natural mechanism.

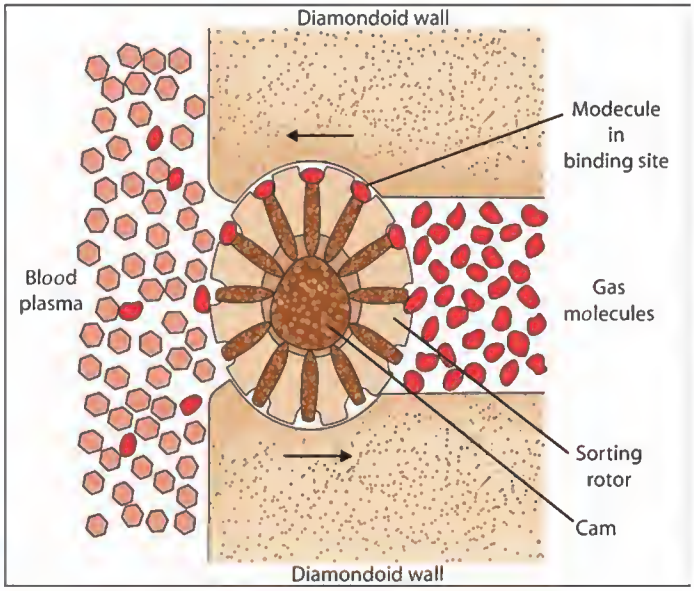

Figure 10: Microbiovore.

Respirocytes

Robert Freitas has designed an artificial mechanical 'respirocyte' (**Figure 11**), which is a one micron size diamondoid 1,000 atmospheric pressure vessel with active pumping powered by endogenous serum glucose. It is able to deliver 236 times more oxygen to the tissue per unit volume than natural RBC and to manage carbonic acidity. Gas concentration sensors on the outside of each device let the nanorobot know when it is time to load O_2 and unload CO_2 (at the lung) or vice versa (at the tissues). Injection of a 5 mL therapeutic dose of 50% respirocyte-saline suspension

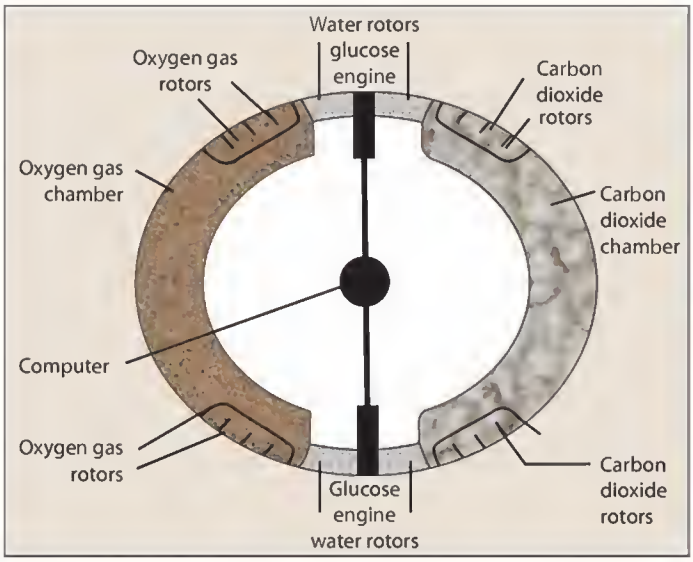

Figure 11: Respirocytes.

delivers 5 trillion respirocytes that can replace the gas carrying capacity of the patient's entire 5 litres of blood.

Vasculoid

The vasculoid (**Figure 12**) is a single complex, multisegmental nanotechnological robotic system capable of duplicating all essential thermal and biochemical transport functions of the blood, including circulation of respiratory gases, glucose, hormones, cytokines, waste products and cellular components. The vasculoid system conforms to the shape of existing blood vessels and serves as a complete replacement for natural blood.

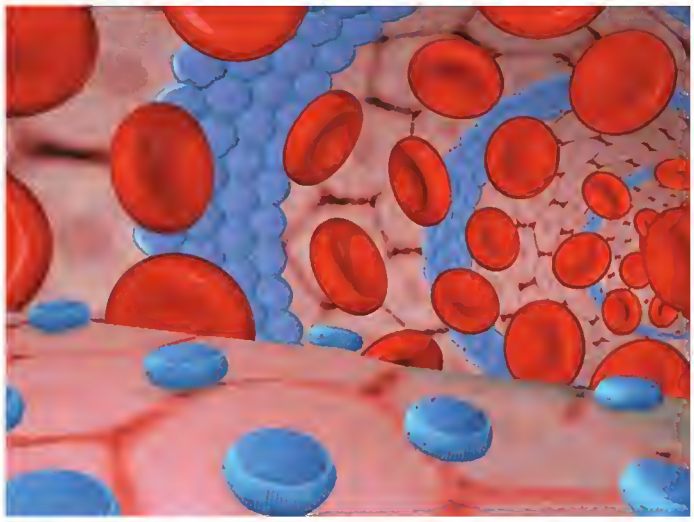

Figure 12: Vasculoid.

Artificial Platelet (Clottocyte)

An artificial mechanical platelet appears to halt bleeding 100 to1,000 times faster than natural haemostasis (**Figure 13**). A single clottocyte reliably detects a blood vessel break and rapidly communicates this fact to its neighbours,

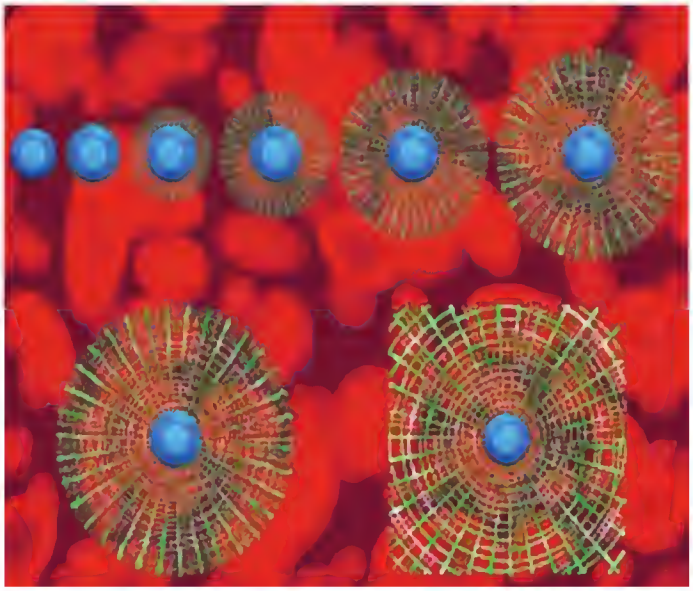

Figure 13: Artificial platelets (Clottocyte).

immediately triggering a progressive controlled mesh-release cascade.

THE FUTURE

Nanotechnology is considered to be a next big wave after information technology and biotechnology according to National Science Foundation (NSF). Revenues from nanotechnology can touch $ one trillion by 2015.

Specialised nanoemulsions, made up of tiny soyabean oil droplets 200 nm in diameter, suspended in water, studded with bits of pathogenic organisms and swabbed into the nose, may be the influenza vaccines of the future. They are taken up by dendritic cells and produce immunity in mucosal tissues of the nose, mouth, lungs.

Animal models of HIV have shown the feasibility of vaginal mucosal immunity by local application of HIV vaccine in mice.

Living systems are governed by molecular behaviour at nanometer scales where the disciplines of physics, chemistry and biology and computer simulation all converge. Detecting gene expression can be made dramatically more efficient through utilisation of nanofabricated surfaces and devices. Expanding our ability to characterise an individual's genetic make up will revolutionise diagnosis and therapy of the individual patient.
